## Abstract

Retinal health and function is dependent on the function of various cell types, and genetic insult or injury to these cells can result in vision loss. The inherited retinal degenerations constitute a heterogeneous group of orphan diseases, with multiple causative genes and highly varied disease phenotypes. Many of the genes involved in photoreceptor degeneration are also involved in development, and understanding both of these facets of photoreceptor health is critical to understanding disease. While photoreceptor death is a leading cause of vision loss, other cell types are also affected in retinal disease. Retinal ganglion cells are also commonly affected in retinal diseases such as glaucoma and optic neuritis, and their axons are myelinated by oligodendrocytes. Because of the importance of myelin, oligodendrocyte health is an additional important aspect of retinal health and vision. Multiple sclerosis, a demyelinating disorder, often presents as optic neuritis, a condition marked by retinal ganglion cell demyelination. As such, a better understanding of oligodendrocyte development and myelination is important for identifying remyelination therapeutic targets. In this study, we utilized stem cell based systems combined with single-cell transcriptomics to better understand development of photoreceptors and oligodendrocytes, as well as photoreceptor degeneration. We utilized retinal organoids differentiated from a patient-derived stem cell line harboring a homozygous mutation in *NRL*, a transcription factor required for rod development and whose loss leads to Enhanced S Cone Syndrome. These organoids lacked rods and had a higher proportion of *OPN1SW*<sup>+</sup> photoreceptors, with the *OPN1SW*<sup>+</sup> cells being separable into two distinct populations. Additionally, we identified *MEF2C* as a candidate regulator of cone development. We also utilized retinal organoids to develop models of Leber Congenital Amaurosis due to loss of either *CRB1* or *RPGRIP1*. We identified distinct histological pathologies in these models and convergence upon *DDIT3* induction as a shared

degenerative pathway, thus making endoplasmic reticulum stress an attractive therapeutic target. Finally, we characterized oligodendrocyte precursor cell development into either oligodendrocytes or astrocytes and identified heterogeneity within the precursor population, as well as transcription factors and microRNAs that could be important in directing formation of oligodendrocytes or astrocytes.

## **Preface**

A huge thanks to everyone in the Zack lab and our collaborators for making this work possible. Especially Don, Cindy, and Xitiz for their continued mentorship and support over the years. I would also like to thank our collaborators in the labs of David Gamm, Jiang Qian, and Jeff Wang for their indispensable contributions to this work.

### **List of Abbreviations**

ALC	Astrocyte lineage cell
CNS	Central nervous system
ER	Endoplasmic reticulum
ESCS	Enhanced S Cone Syndrome
GO	Gene ontology
hESC	Human embryonic stem cell
hPSC	Human pluripotent stem cell
ICC	Immunocytochemistry
IHC	Immunohistochemistry
iPSC	Induced pluripotent stem cell
KO	Knockout
LCA	Leber Congenital Amaurosis
MS	Multiple Sclerosis
OL	Oligodendrocyte
OLLC	Oligodendrocyte lineage cell
ONL	Outer nuclear layer
OPC	Oligodendrocyte precursor cell
scRNAseq	Single cell RNA sequencing
TF	Transcription factor
t-SNE	T-distributed stochastic neighbor embedding
UMAP	Uniform manifold approximation and projection
UMI	Unique molecular identifier
WT	Wild type

## **Chapter 1: Introduction**

The neural retina is critical for visual function, with light detection first occurring in photoreceptors followed by signal transduction via the optic nerve to the brain (1, 2). This process and overall retinal health depends on proper function and coordinated activity of the many cell types of the retina, including photoreceptors, bipolar cells, amacrine cells, horizontal cells, retinal ganglion cells, muller glia, and retinal pigmented epithelium (3). Retinal health and vision are susceptible to a multitude of genetic and environmental insults, and retinal disease can present with both Mendelian and non-Mendelian inheritance patterns (4). There is vast heterogeneity in the causes of retinal degenerations in the cells affected, role of environmental factors, phenotypic presentation and severity, genes mutated, and the specific mutant alleles. This heterogeneity complicates treatment of retinal diseases, as many individuals globally are affected, but they vary significantly in the cause of their retinal dysfunction. To understand retinal disease, it is critical to also understand retinal development. Development and degeneration are closely linked, with many genes important for development involved in retinal degeneration (5-8).

I sought to better understand both of these facets of retinal health through analysis of human models of both development and degeneration. Many different retinal pathologies have been described, with Enhanced S Cone Syndrome (ESCS) representing a sort of developmental defect and Leber Congenital Amaurosis (LCA) representing the most severe form of photoreceptor degeneration (9-12). ESCS is inherited in an autosomal recessive manner and patients usually lack the transcription factor NR2E3, or occasionally NRL, the transcription factor upstream of NR2E3 (11-13). The combined functions of NRL and NR2E3 are critical for rod photoreceptor development, and loss of either leads to development of an apparent cone-dominant

retina. Patients with ESCS manifest with enhanced blue cone function and an absence of rod function, as well as some degree of retinal degeneration (11, 12). As ESCS presents more of a developmental aberration than a degeneration, this disease provides an attractive model to study cone development and the results of loss of a critical developmental transcription factor. While mouse models of *Nrl* loss have been studied extensively, the work here represents the first molecular investigation of *NRL* loss using a human model (14-18). Additionally, previous studies had analyzed population transcriptomics in describing *Nrl* null photoreceptors, while this study presents in depth single-cell transcriptomic characterization which enabled discovery of subpopulations of *NRL* null photoreceptors.

On the other end of the disease spectrum is LCA, a severe photoreceptor degeneration in which patients are either born blind or suffer significant vision loss within the first year of life (9, 10). There are over 20 genes known to cause LCA, which can present with either autosomal recessive or autosomal dominant inheritance patterns (9). In addition to the genetic heterogeneity of LCA, there is also heterogeneity in the affected cell type, with mutations affecting either photoreceptors or retinal pigmented epithelium function. Dysfunction of either of these cell types can lead to photoreceptor cell death. Additionally, LCA can vary in whether rod or cone photoreceptors are more severely affected (9, 10). Many mouse models of LCA have been described, and recently there have been efforts to characterize human models of LCA, specifically LCA caused by mutation of *CEP290* and *AIPL1* (19-26). While there have been advances in LCA treatment, specifically the success of *RPE65* gene therapy, the inherited retinal degenerations remain largely untreatable (27). In this work, I sought to characterize *CRB1* and *RPGRIP1* knockout LCA disease models and identify possible degenerative pathways targetable for treatment strategies. Better understanding of both

developmental and degenerative diseases can provide critical insights into photoreceptor health and possibly identify targets for therapeutic intervention.

While photoreceptor degeneration is a major cause of vision loss, it is also important to better understand the other cell populations important for retinal health. Specifically, retinal ganglion cells, whose axons form the neuronal component of the optic nerve and ultimately transmit visual signals to the brain, are also frequently affected in retinal disease (28, 29). In addition to cell stress within the retinal ganglion cells themselves, demyelination can also promote cell death and visual impairment (30). Myelination insulates the axons of neurons and aids in nerve conduction, with oligodendrocytes myelinating cells of the central nervous system, including retinal ganglion cells (31). Loss of myelin in the central nervous system occurs in Multiple Sclerosis, and a subset of patients experience optic neuritis in which retinal ganglion cell demyelination occurs (32). As such, a better understanding of oligodendrocyte development may provide insights into myelination and possible treatment avenues. Many recent studies have isolated and characterized both human and murine oligodendrocytes, while this study describes the development of stem cell derived oligodendrocyte precursor cells (OPCs) and characterizes their possible cell fates (33-35). By understanding how oligodendrocytes develop and begin expressing myelin, it may be possible to promote myelination in diseased tissue. Myelination and its relationship to retinal ganglion cell health is an additional aspect of retinal health and disease that warrants further investigation.

Rapidly evolving molecular biology and genetics tools such as stem cell differentiation strategies and single cell RNA sequencing (scRNAseq) have enabled important advances in disease research. While mouse models have provided many insights into development and disease, stem cell differentiation allows for studying these processes in a human system. Stem cell derived retinal organoids have become an

important human model to characterize retinal development and disease (22, 23, 36-51). Retinal organoids develop all major cell types of the retina and closely mimic *in vivo* retinal architecture, with an organized outer nuclear layer (ONL) of photoreceptors capable of responding to light stimuli (51). Many recent studies have used retinal organoids to describe both retinal development and disease, providing important complementary insights to mouse models. In addition to 3D organoid models, 2D culture systems can provide important insights into how a specific cell population develops. Stem cell derived OPCs are an attractive model for studying oligodendrocyte development and myelination, as OPCs are not abundant *in vivo* and there are distinct differences in murine vs human OPCs development (52, 53). While murine OPCs are fated to form oligodendrocytes, human OPCs are not restricted to solely oligodendrocyte fates, thus human models can provide important insights not possible in mouse models (52, 53). In addition to stem cell strategies, scRNAseq has become an invaluable tool to investigate retinal biology. Recent studies have utilized scRNAseq to characterize retinal development in murine retinas, human retinal organoids, primate retinas, and human fetal and adult retinas (37, 44, 46, 50, 54-60). The combinatorial use of stem cell differentiation strategies and scRNAseq provides a model to investigate human development and disease at high resolution and identify critical transcriptomic alterations in a population-specific manner, thus providing an attractive system for retinal disease research.

In this study, scRNAseq and stem cell differentiation strategies were used to investigate three critical aspects of retinal health. First, I analyzed the transcriptomic alterations resulting from loss of NRL in patient derived retinal organoids to characterize photoreceptor development in ESCS. In the absence of NRL, rods development does not occur, and instead the retinal organoids have a higher abundance of S opsin+ photoreceptors. However, these photoreceptors fall into two discrete populations, one

population more representative of typical S cones and the other being rod-cone intermediates, or “cods.” The cod population exhibited high S opsin expression, but lack of substantial rod or cone gene expression profiles and a great degree of differential gene expression when compared to both rods and cones. In addition to the cod population, we identified MEF2C as a candidate regulator of cone development or maturation due to its RNA and protein expression pattern. Second, I generated stem cell lines harboring CRB1 or RPGRIP1 null alleles to model a time course of LCA in retinal organoids with the goal of identifying common degenerative pathways that could be therapeutically targeted. Both models exhibited distinct histological aberrations, the RPGRIP1 KO photoreceptors incapable of outer segment disc morphogenesis and CRB1 KO mature rhodopsin expressing rods mislocalized within the RCVRN+ ONL. Despite exhibiting different histological changes, both KO's induced DDIT3 and the endoplasmic reticulum (ER) stress pathway. While the onset and duration of ER stress varied across the two KO's, possibly resulting from the different temporal expression patterns of CRB1 and RPGRIP1, this represented a common degenerative pathway that may provide targets for therapeutic intervention for LCA and other photoreceptor degenerations involving ER stress. Finally, we characterized development of stem cell derived OPCs into either astrocytes and oligodendrocytes. By analyzing the developmental trajectory reconstructed from 3 time points, we identified possible transcription factors and microRNAs important for regulating this cell fate decision. This study also verified that, unlike the mouse, human OPCs have the potential to form either astrocytes or oligodendrocytes and this branch in cell fate can be recapitulated *in vitro*. Collectively, this work has created a more detailed picture of human retinal health and disease, taking into account both development and degeneration across various models.

## **Chapter 2: Photoreceptor development in a human model of NRL loss**

### **Investigating cone photoreceptor development using patient-derived NRL null retinal organoids**

#### **Abstract**

Photoreceptor loss is a leading cause of blindness, but mechanisms underlying photoreceptor degeneration are not well understood. Treatment strategies would benefit from improved understanding of gene-expression patterns directing photoreceptor development, as many genes are implicated in both development and degeneration. Neural retina leucine zipper (NRL) is critical for rod photoreceptor genesis and degeneration, with *NRL* mutations known to cause enhanced S-cone syndrome and retinitis pigmentosa. While murine *Nrl* loss has been characterized, studies of human NRL can identify important insights for human retinal development and disease. We utilized iPSC organoid models of retinal development to molecularly define developmental alterations in a human model of NRL loss. Consistent with the function of NRL in rod fate specification, human retinal organoids lacking NRL develop S-opsin dominant photoreceptor populations. We report generation of two distinct S-opsin

expressing populations in NRL null retinal organoids and identify *MEF2C* as a candidate regulator of cone development.

## Introduction

Normal visual function requires light detection by photoreceptors followed by signal transduction through the neural retina to the brain. Mammalian retinas contain rod and cone photoreceptors, with rods responsible for dim-light and peripheral vision and cones for color, high acuity, and central vision. Rods and cones arise from a common precursor, and photoreceptor cell fate is dictated by key transcription factors (61). Neural retina leucine zipper (NRL) is required for rod development, and it activates Nuclear Receptor Subfamily 2 Group E Member 3 (NR2E3), which suppresses expression of cone-specific genes, promoting the rod developmental program (13). Previous murine studies have shown that *Nrl* loss leads to development of cone dominant retinas; specifically, an increase in S-cones (17).

Like the murine phenotype, loss of NRL in humans can cause enhanced S-cone syndrome, a rare retinal disease characterized by supranormal blue cone function due to an increased proportion of S-cones and night blindness due to the absence of rods (11, 12). However, the range of clinical phenotypes caused by *NRL* mutations is broad, with dominant missense mutations leading to a clinical picture more akin to retinitis pigmentosa (11, 12, 62). Similarly, enhanced S-cone syndrome can result from mutations in genes other than *NRL*, usually *NR2E3*. Using an induced pluripotent stem cell (iPSC) line derived from a patient carrying a homozygous *NRL* mutation, we sought to characterize the developmental and molecular effects of NRL loss in human stem cell-derived retinal organoids. Retinal organoids, which closely mirror *in vivo* retinal development, provide a human model for studying retinal development and degeneration (36, 40, 42, 45, 49, 51, 63-70). Organoids closely mimic retinal structure and apical-

basal polarity, with an outer layer of photoreceptors capable of ribbon synapse formation and inner layers of retinal ganglion, amacrine, horizontal, and bipolar cells.

In addition to histological characterization of human retinal organoids, transcriptomics, particularly at the single-cell level, can identify and characterize distinct cell populations. Dropseq, a single-cell RNA sequencing (scRNAseq) method utilizing microfluidics and barcoded beads to capture the transcriptomes of single cells, has proven powerful for characterizing mouse retinas and identifying subtypes of mouse bipolar cells (57, 59). More recently, scRNAseq studies with developing and adult retinal tissue have offered insight into *in vivo* human retinal cell populations (55, 56, 60). While previous studies have utilized scRNAseq to identify cell types of developing retinal organoids, they have not discerned distinct photoreceptor sub-populations (37, 44, 46). Additionally, while transcriptomics have been used to characterize *Nrl* loss in murine photoreceptors, these analyses were not performed at a single-cell level, thus limiting the potential to identify and characterize sub-populations (16, 71, 72).

Here, we present histological and single-cell transcriptomic characterization of human iPSC-derived retinal organoids with and without functional *NRL* (73). We show that retinal organoids lacking *NRL* develop S-opsin<sup>+</sup> dominant photoreceptor populations. In contrast to previous studies, we provide evidence that, in the absence of *NRL*, two distinct populations of S-opsin expressing photoreceptors emerge; one population more representative of typical cones, and the other of rod/cone intermediates. Finally, our analyses identified a putative novel regulator of cone photoreceptor development. This study further defines photoreceptor subpopulations in a human model of *NRL* loss and provides a platform for characterizing aberrant photoreceptor development.

## **Methods**

### **Generation of iPSC lines:**

Tissue samples were obtained with written informed consent in adherence with the Declaration of Helsinki and with approval from institutional review boards at the University of Wisconsin-Madison and Massachusetts Eye and Ear Infirmary. The patient received clinical ophthalmic care from Dr. Eric Pierce in the ophthalmology clinic at the Children's Hospital of Philadelphia. The patient was recruited by Dr. Pierce to participate in research on the genetics of inherited retinal diseases. Participation involved consenting to collection of both blood and tissue samples. Informed consent was obtained from all donors of cells and tissues. A fibroblast biopsy from patient OGI-019-047 was reprogrammed via Sendai virus delivery of *OCT3/4*, *KLF4*, *SOX2* and *cMYC* by the Waisman Center iPSC core (University of Wisconsin-Madison) (73). The patient mutation (*NRL* c.233dup(C),p.(L75Pfs19X)) was confirmed in iPSCs and organoids by PCR amplifying a 770 nt genomic region surrounding the duplication with F-5'-TCCCTGCTCCTGGTTC-3' and R-5'-CACCATCCCTCTGGCTTTCC-3' followed by Sanger sequencing (University of Wisconsin Biotech Center, Madison, WI) with the F primer. Karyotype analysis was performed on iPSCs by WiCell (Madison, WI).

### **Cell lines and retinal differentiation:**

Three independent clones were used for all experiments and compared to three WT lines: WA09 (WiCell), 1013 and 1581 (36). All plasticware and reagents unless otherwise stated, were from ThermoFisher. All hPSCs were maintained on Matrigel in either mTeSR1 (WiCell) or StemFlex and passaged with either Versene or ReLeSR (STEMCELL Technologies). Retinal differentiation has been described (36). Briefly, embryoid bodies (EB) were lifted with either 2 mg/ml dispase or ReLeSR and weaned

into Neural Induction Media (NIM: DMEM:F12 1:1, 1% N2 supplement, 1x MEM nonessential amino acids (MEM NEAA), 1x GlutaMAX and 2 mg/ml heparin (Sigma)) over the course of 4 days. On day 6 (d6), 1.5 nM BMP4 (R&D Systems) was added to fresh NIM and on d7, EBs were plated on Matrigel at a density of 200 EBs per well of a 6-well plate. Half the media was replaced with fresh NIM on d9, d12 and d15 to gradually dilute the BMP4 and on d16, the media was changed to Retinal Differentiation Media (RDM: DMEM:F12 3:1, 2% B27 supplement, MEM NEAA, 1X antibiotic, anti-mycotic and 1x GlutaMAX). On d25-30, optic vesicle-like structures were manually dissected and maintained as free floating organoids in poly HEMA (Sigma)-coated flasks with twice weekly feeding of 3D-RDM (RDM + 5% FBS (WiCell), 100 uM taurine (Sigma) and 1:1000 chemically defined lipid supplement) to which 1 uM all-trans retinoic acid (Sigma) was added until d100. Live cultures were imaged on a Nikon Ts2-FL equipped with a DS-fi3 camera or on a Nikon Ts100 equipped with a qImaging CE CCD camera.

#### **Immunocytochemistry and transmission electron microscopy:**

Human prenatal eyes were obtained from the Laboratory of Developmental Biology (University of Washington-Seattle). Tissue collection methods adhered to Institutional Review Board requirements, NIH guidelines and the Helsinki declaration. Organoids were fixed in 4% paraformaldehyde at room temperature for 40 min, cryopreserved in 15% sucrose followed by equilibration in 30% sucrose, and sectioned on a cryostat. Slides were blocked for 1 hr at RT in 10% normal donkey serum, 5% BSA, 1% fish gelatin and 0.5% Triton then incubated overnight at 4°C with primary antibodies diluted in block. Supplementary Table 2 lists primary antibodies, dilutions and sources. Slides were incubated with species-specific fluorophore-conjugated secondary antibodies diluted 1:500 in block, for 30 minutes in the dark at RT (Alexa Fluor 488, AF546 and AF647). For co-visualization of ML and S opsin, the rabbit  $\alpha$ -ML opsin

antibody (Millipore) was directly conjugated to AF555 using the Apex Alexa Fluor 555 labeling kit (ThermoFisher) according to manufacturer's instructions, mixed with unlabeled rabbit  $\alpha$ -S opsin (Millipore) and detected with an anti-rabbit AF488 secondary. Sections were imaged on a Nikon A1R-HD laser scanning confocal microscope. Cone and rod counts were performed on at least 6 random images from at least 3 different organoids from each of the 3 WT lines and each of the 3 L75Pfs clones using Nikon Elements D annotations and measurements module. *P*-values were calculated with an unpaired two-tailed Student's *t*-test (Mann-Whitney test) using Graph-Pad Prism 6.

Organoids were fixed for TEM in 3% glutaraldehyde and 1% paraformaldehyde in 0.08M sodium cacodylate buffer (all from Electron Microscopy Sciences) overnight with gentle rocking at 4°C, washed with 0.1M cacodylate buffer and post-fixed in 1% Osmium Tetroxide for 2 hrs at RT. The organoids were dehydrated in a graded ethanol series, further dehydrated in propylene oxide and embedded in Epon epoxy resin. Ultra-thin sections were cut with a Leica EM UC6 Ultramicrotome and collected on pioloform-coated 1 hole slot grids (Ted Pella, Inc.). Sections were contrasted with Reynolds lead citrate and 8% uranyl acetate in 50% EtOH and imaged on a Philips CM120 electron microscope equipped with an AMT BioSprint side-mounted digital camera and AMT Capture Engine software.

#### **RT-qPCR:**

Stage 2/3 organoids from two differentiations each from three WT and 3 L75Pfs clones were collected at d160 (when PRs were starting to mature) and RNA was extracted using the RNAeasy mini spin kit (Qiagen) according to manufacturer's instructions, including the optional DNase step. 1 ug of RNA was reverse transcribed using the iScript cDNA synthesis kit (BioRad), diluted 1:10 and qPCR was performed

with SSO Advanced Sybr Green Master mix (BioRad) on a StepOne Plus qPCR machine (ABI). A list of primers can be found in Supplementary Table 3.  $\Delta C(q)$ s were calculated from the geometric mean of two housekeeping genes and variability for all six lines was visualized by subtracting the  $\Delta C(q)$  for each differentiation from the avg  $\Delta C(q)$  for all six WT samples.  $2^{-\Delta\Delta C(q)}$  were plotted and *P*-values were calculated using an unpaired two-tailed Student's *t*-test (Mann-Whitney test) using Graph-Pad Prism 6.

#### **Lentiviral rescue:**

Full length human NRL coding sequence was PCR-amplified from human adult neuroretina cDNA using F-5'-ATGGCCCTGCCCCCAGC-3' and R-5'-TCAGAGGAAGAGGTGGGAGGGGTC-3' with a BamHI site added 5' and a Sall site added 3' to facilitate cloning into the pSIN-WP-mpgk lentiviral shuttle vector (74). Lentivirus was produced via transfection of HEK293T cells, concentrated 40-fold by ultracentrifugation and titered on hiPSCs to calculate a working titer (75). D90, early stage 2 organoids were infected every 3 days 3 times with effective titer to give >70% infection of iPSCs, by adding virus to the media. Control pgkGFP virus infection was monitored by live fluorescence. Organoids were maintained in culture for 100 days to allow sufficient time for RHO expression, whereupon they were fixed and processed for ICC as described above. The pgkNRL infection was repeated 4 times- once with each clone except for clone 7 which was infected twice.

#### **Single cell dissociation and sample preparation:**

At d100, cell lines used were 1013 and 1581 for WT and L75Pfs clones 9 and 11. D170 organoids were 1013 for WT and clones 7 and 9 for L75Pfs. Organoids were dissociated to single cells with papain (Worthington) to 1 mg/ml and 5 uL DNase (Roche) per mL, using 200 uL papain mix per organoid. After 1-2 hours when organoids

appeared fully dissociated the reaction was quenched with media containing 10% FBS (Gibco). Single cells were resuspended in HBSS (Gibco) and 0.1 mg/mL BSA at 120,000 cells per mL. Single cell capture was performed using a home-made Dropseq setup according to the published Dropseq protocol (57)<sup>21</sup>. Cells were combined in oil (Biorad) and barcoded beads (Chemgenes) in ~1 nL droplets. Droplets were broken using 6x SSC and perfluorooctanol (Sigma) to collect beads. Reverse transcription was performed using Maxima reverse transcriptase (Thermo Fisher Scientific) and cDNA was amplified using Kapa (Roche). cDNA was quantified using a Bioanalyzer DNA High Sensitivity Chip (Agilent). cDNA was fragmented and libraries were created using the Nextera XT library prep kit (Illumina). Libraries were quantified by Qubit dsDNA HS (Thermo Fisher Scientific) and sequenced via Illumina HiSeq 2500.

### **Bioinformatics:**

Fastq files were processed according to the published Dropseq analysis pipeline and aligned to GRCh38 to extract expression matrices. Canonical component analysis, t-distributed stochastic neighbor embedding, and clustering was performed using the Seurat R package (version 2) (76). To remove low quality cells, cells with less than 200 genes or greater than 20% (d170) or 15% (d100) mitochondrial RNA content were filtered out. Genes expressed in a minimum of 2 cells were included for downstream analysis. The union of the top 2000 highly variable genes of WT and L75Pfs were used for canonical component analysis and 20 (d170) and 17 (d100) canonical components and were used to align subspaces and cluster cells. Cell populations were identified using previously published marker genes (Supplementary Table 1) and differential gene expression analysis was performed within each cluster to identify genes that varied by genotype. Differential expression analysis within each population between WT and L75Pfs cells was performed using a Wilcoxon rank sum test. Bonferroni corrected p-

values were calculated using the number of genes expressed at each time point (23645 for d100 and 25622 for d170). Cell populations at each age were compared to published fetal retinal cell populations and adult peripheral versus foveal populations (55, 60). For each population, the average expression of each gene expressed in both datasets was input for correlation analysis. Spearman correlation tests were performed for each cell population against its corresponding fetal and adult populations. Photoreceptor clusters of d100 and d170 were subsetted out for analysis using the Monocle R package (version 2) (77). A semi-supervised differential gene expression test was used on WT cells to identify genes that varied by age and cell type (NR2E3=rod, ARR3=cone, neither=undifferentiated photoreceptor). The top 780 non ribosomal or mitochondrial genes were used for ordering and trajectory reconstruction for both the WT trajectory and combined trajectory. Differential gene expression analysis was performed on the node in the WT trajectory to identify genes with rod/cone branch dependent expression. Similar analyses were performed on published adult photoreceptors (60). Peripheral and foveal photoreceptors combined, and rod/cone designations were retained for the analysis. A differential gene expression test was performed to identify genes differentially expressed across cell types, and genes with q values < 0.00001 (602 genes) were used for trajectory reconstruction. Additional differential gene expression tests were performed on subsets of the merged trajectory to characterize L75Pfs photoreceptors compared to WT rods and cones. All differential gene expression analysis in Monocle was performed using a likelihood ratio test on the 14,657 genes expressed in a minimum of 10 cells and a Bonferroni corrected p-value. To analyze possible regulation by MEF2C, human retinal ATAC-seq data was queried for genes with MEF2C binding sites (78). The resulting gene list (475 genes with MEF2C binding sites) was compared against genes expressed in at least 10 cells of the photoreceptor dataset (14,657 genes) and against genes differentially expressed (791 genes) between the WT

cones and L75Pfs rod-like cells. The percentage of expressed genes and differentially expressed genes with MEF2C binding sites were compared against the expected percentages using a two-tailed Student's T test. To estimate expected frequency in expressed genes, 14,657 genes were randomly chosen from all 28,040 human genes and the number of genes with MEF2C binding sites was determined and this process was repeated for 1000 iterations. This process was repeated for differentially expressed genes, randomly choosing 791 genes of the 14,657 expressed genes to determine the expected frequency of differentially expressed genes with MEF2C binding sites.

## **Results**

### **Differentiation of patient and control retinal organoids**

Fibroblasts from a patient with a homozygous null mutation, a frame shift and premature stop (c.223dupC, p.L75Pfs\*19) in the *NRL* gene, were reprogrammed to hiPSCs (73). Three independent, karyotypically normal L75Pfs clones (Supplementary Fig. 1) were compared with WA09 and two wildtype (WT) hiPSC lines (1013 and 1581) (36). All lines were indistinguishable in their ability to make stage 1 organoids, characterized by a phase bright, neuroepithelial appearance and the presence of ganglion cells and proliferative retinal progenitor cells (Supplementary Fig. 2) (36). CRX+/RCVN+ photoreceptor precursor production was comparable between early stage 2 WT and L75Pfs organoids, when photoreceptor subtype specification begins (Fig. 1; compare Fig. 1B, 1C, merge in 1E to 1G, 1L, 1Q, 1H, 1M, 1R, merges in 1J, 1O and 1T) (36). However, NRL+ rod photoreceptors were never detected in L75Pfs organoids (compare Fig. 1D to 1I, 1N and 1S). As photoreceptors matured and formed outer segments (the "hair-like" surface projections in Figure 2C and 2I), L75Pfs organoids showed a striking S-opsin dominant photoreceptor phenotype (Fig. 2) (36). Unlike WT organoids, which possess a single layer of ML-opsin+ cones and rare S-opsin+ cones

along the outermost aspect of the outer nuclear layer (ONL) (Fig. 2A), L75Pfs organoids contained S-opsin expressing cells throughout the ONL and in greater abundance than ML-opsin expressing cells (Fig. 2B; also compare Fig. 2E, 2G to Fig. 2K, 2M). Quantification of ARR3<sup>+</sup> cones and NR2E3<sup>+</sup> rods as a percent of total nuclei in the ONL (Fig. 2D-H and J-N) revealed a dramatic reduction in rods and an increase in cones in the L75Pfs ONL (Fig. 2O). Interestingly, while WT organoids had rare ARR3<sup>-</sup>/NR2E3<sup>-</sup> nuclei in the ONL, ~20% of the L75Pfs ONL nuclei expressed neither marker. Since ARR3 is normally expressed >60 days after cone progenitors are detected, these ARR3<sup>-</sup>/NR2E3<sup>-</sup> cells may represent rod progenitor-derived cells that either have not committed to a cone fate or do not yet express ARR3. We quantified the ML- or S-opsin expressing cells as a fraction of the total ARR3<sup>+</sup> cells and detected a 38-fold shift in the ML:S-opsin cone ratio, from 19:1 in WT to 1:2 in L75Pfs organoids (Fig. 2P). Additional analyses of rod and cone gene expression by RT-qPCR revealed that rod developmental genes were downregulated in L75Pfs organoids relative to WT organoids, while S-opsin expression was significantly increased in the L75Pfs organoids (Fig. 2Q,  $p < 0.005$ , Mann-Whitney test). Thus, in L75Pfs human retinal organoids, rods appeared shifted toward an S-cone fate, consistent with the *Nrl*<sup>-/-</sup> mouse phenotype (15, 17). Finally, we examined the inner nuclear layer (INL) of L75Pfs organoids and found it indistinguishable from WT organoids (Supplementary Fig. 3A-N), including comparable production of PKC $\alpha$ <sup>+</sup> rod bipolar cells (consistent with the *Nrl*<sup>-/-</sup> mouse phenotype) (79). However, in contrast to the *Nrl*<sup>-/-</sup> mouse, L75Pfs organoids displayed an intact outer limiting membrane (OLM) with no increase in rosette formation compared to WT organoids (Supplementary Fig. 3O-Y) (17, 80).

### **Reintroduction of WT NRL restores rod formation**

To confirm that the observed L75Pfs phenotypes were indeed due to lack of NRL, we introduced functional *NRL* to determine whether NRL expression could rescue the phenotype. We ectopically expressed WT *NRL* in d90 L75Pfs retinal organoids using a lentivirus expression cassette. Of note, d90 corresponds to the onset of NRL protein detection in WT organoids (36). After 100 additional days in culture, organoids transduced with virus containing either a control *GFP* expression cassette (without *NRL*) or a WT *NRL* expression cassette were examined by immunocytochemistry for NRL, rhodopsin (RHO), and S-opsin expression. Figure 3A-D shows co-expression of GFP in ARR3+ cones of control cassette-treated L75Pfs NRL organoids, which remained NRL-/RHO- and expressed S-opsin throughout the ONL (Fig. 3E-L), similar to untreated L75Pfs organoids. In contrast, WT *NRL* expression cassette-treated organoids showed NRL protein in patches of nuclei within the ONL (Fig. 3M-X). Furthermore, all cells with restored NRL expression did not express S-opsin (Fig. 3M-T). Additionally, rare RHO+ cells (Fig. 3Q and 3W), which were never observed in untreated or pgkGFP-transduced (Fig 3I-L) L75Pfs organoids, were observed and were uniformly negative for S-opsin (Fig. 3T) and ARR3 (Fig. 3X). Of note, the localization of RHO to outer segments in some lenti-pgkNRL transduced cells (Fig. 3W) is reminiscent of RHO immunostaining in WT organoids (Supplementary Figure 4A-D). Thus, restoring NRL protein expression to L75Pfs photoreceptor precursor cells restricted S-opsin expression and could promote, although at low efficiency, RHO expression.

### **scRNAseq to identify and analyze organoid cell types**

After establishing that the observed L75Pfs phenotype was due to NRL loss, we sought to identify and transcriptomically analyze the cell populations in WT and L75Pfs retinal organoids. We performed scRNAseq via the Dropseq platform on WT and L75Pfs organoids differentiated to early (100-103 days) or late (170 days) stage 2 (36,

57). At the earlier time, 4 WT and 4 L75Pfs organoids yielded transcriptional profiles of 5,294 and 4,787 cells, respectively. Cells were clustered by t-distributed stochastic neighbor embedding (tSNE) using the Seurat R package (76). The even distribution of cells classified either by number of genes expressed or number of unique molecular identifiers (UMIs) throughout the clusters confirmed that these factors were not driving clustering (Supplementary Fig. 5). Rather, based on known marker genes (Supplementary Table 1, Supplementary Fig. 6), the clusters represent stereotypical retinal populations present in both WT and L75Pfs organoids (Fig. 4A). Both rod and cone photoreceptors were present, with almost all *NR2E3* expressing cells being WT (Fig. 4B). Spearman correlations were performed between WT cells of each population and published fetal and adult retinal scRNAseq datasets (Supplementary Fig. 7-8) (55, 60). This analysis revealed d100 organoids yielded amacrine, horizontal, and retinal ganglion cells more similar to fetal retinal populations. Rods most closely resembled adult peripheral rods, while cones and Müller glia more closely resembled adult foveal cells. Differential gene expression tests were performed between WT and L75Pfs cells of each cluster, and genes with significantly different expression and an average natural log fold change greater than 0.5 (~1.6 fold) are summarized in Supplementary Data 1. Of genes enriched in L75Pfs cells of the rod cluster, the presence of the cone transducin, *GNGT2*, indicates that this population is acquiring a cone-like profile.

At d170, 3 WT and 6 L75Pfs organoids yielded 8,920 and 15,447 single cell transcriptomes, respectively. Cell populations identified by marker gene expression (Supplementary Table 1) showed that mature retinal cells were captured, including bipolar cells and opsin-expressing photoreceptors (Fig. 4C, Supplementary Fig. 9). Loss of retinal ganglion cells was also observed. Possible explanations for retinal ganglion cell loss include microfluidic bias favoring other cell types or death of retinal ganglion cells due to the lack of vasculature in retinal organoids. Notably, age-dependent retinal

ganglion cell loss has been reported in retinal organoids (36). Again, Spearman correlations were performed between WT cells of each population and published fetal and adult retinal scRNAseq datasets (Supplementary Fig. 10-11) (55, 60). Like d100, organoids at d170 yielded amacrine and horizontal cells more similar to fetal cells. Rods and bipolar cells more closely resembled adult peripheral cells, and, similarly to d100, cones and Müller glia were more highly correlated with adult foveal cells. Two cone opsin-expressing populations were identified, one that expressed both ML-opsin and S-opsin and the other consisting of cells that primarily express S-opsin. Due to the identity of the M- and L-opsin 3' UTRs that were captured via our analysis, we could not distinguish between M- and L-opsin transcripts. Interestingly, 1.5% of WT cone opsin-expressing cells co-expressed both ML- and S-opsin (Fig. 4D). The number of UMIs and genes expressed by these cells suggests they are not doublets (Fig. 4E).

We performed differential gene expression analysis on these 3 cone opsin-expressing populations (ML-, ML/S-, or S- expressing) to identify novel markers of developing cone subtypes. As expected, there were only minimal differences in gene expression between the cone populations. We identified *MYL4* as a possible ML-cone marker and *CCDC136* and *DCT* as possible S-cone markers (Fig. 4F). *CCDC136* is preferentially expressed in mouse S- and S/M-cones and recently has been shown to be enriched in primate S-cones (58, 81). Interestingly, Peng et al. identified *MYH4*, the heavy chain complement to *MYL4*, as a transcript distinguishing ML-cones from S-cones (58). *NUP93*, *SLC12A6*, *PDRG1*, and *TRAPP2CL* were significantly enriched in the ML/S-cone population compared to the ML or S- expressing cell populations. Further studies are necessary to determine if this ML/S-co-expressing cone population exists *in vivo*.

To determine altered transcriptional profiles at d170, within each cell population we identified differentially expressed genes with an average natural log fold change

greater than 0.5 (~1.6-fold) between WT and L75Pfs cells (Supplementary Data 2).

Within the rod cluster, WT cells had significantly higher expression of many rod-specific genes including *GNAT1*, *ROM1*, *SAMD7*, *NR2E3*, *CNGB1*, *GNB1*, and *PDE6G*, while cone-specific phosphodiesterase, *PDE6H* (Fig. 4G), was enriched in L75Pfs cells, suggesting a more cone-like character of these cells. Despite loss of NRL protein, the *NRL* transcript is still detectable in L75Pfs cells, possibly due to the presence of transcripts that have yet to be removed by nonsense mediated decay. Of differentially expressed genes in the S-opsin expressing population (Fig. 4H), L75Pfs S-opsin expressing photoreceptors were enriched for *OPN1SW* and *GNGT1*, a rod-enriched transducin (Fig. 4G). Despite enrichment of *MYL4* in WT compared to L75Pfs S-cones, this gene exhibited substantially higher expression in ML-cones compared to S-cones, supporting its designation as enriched in ML-cones (Fig. 4F). To identify whether NRL loss alters the distribution of photoreceptor subtypes, we compared expression of *OPN1SW*, *OPN1MW*, and *NR2E3* within each cell population of d170 WT and L75Pfs organoids, as well as total expression of these genes across both genotypes (Fig. 4I). *OPN1SW* was detected in more cells and more clusters in L75Pfs organoids compared to WT, while *OPN1MW* was primarily detected in only the cone cluster of both the WT and L75Pfs organoids. Since NRL activates *NR2E3* transcription, L75Pfs organoids had (as expected) lower expression of *NR2E3* and fewer *NR2E3* expressing cells compared to WT. Quantification of *OPN1SW*, *OPN1MW*, and *NR2E3* expression levels and percentage of expressing cells in d170 organoids can be found in Table 1. Although WT and L75Pfs organoids had significantly different relative numbers of cells expressing *OPN1SW* vs *OPN1MW*, on an individual cell basis the *OPN1SW* and *OPN1MW* expressing cells expressed comparable levels of *OPN1SW* and *OPN1MW*. However, for *NR2E3*, both the percentage of expressing cells and the expression level within individual expressing cells was significantly lower in L75Pfs cells. Taken together, this

data suggests that NRL loss has a profound effect on rod development, shifting them towards an S-cone identity.

### **Trajectory reconstruction of WT photoreceptor development**

After identifying retinal populations, we used the 5,144 WT photoreceptors identified from both time points to create a pseudotemporal trajectory of WT photoreceptor development (77). While the population contained contaminating bipolar cell precursors (44/5,144 cells with *VSX1* or *VSX2* expression), this small population is unlikely to impact trajectory construction (we could have removed these cells, but felt that selectively removing small subpopulations of cells was more likely to produce an artifact than leaving them in). To determine the gene set for ordering the trajectory, we performed a semi-supervised differential gene expression test for genes varying by age and assigned cell type within the WT photoreceptor dataset. After removing mitochondrial and ribosomal genes, the top 780 genes by p-value were used for ordering (Supplementary Data 3). Importantly, neither *VSX1* nor *VSX2* were present in this list, verifying that the contaminating bipolar cells did not affect the trajectory reconstruction. The resulting WT trajectory had one node separating rod and cone photoreceptors, with *OPN1SW* or *OPN1MW* expressing cells in state 2 and *NR2E3/SAG* expressing cells in state 3 (Fig. 5A-D). 590 genes were significantly differentially expressed at this node and the top 100 non-ribosomal genes were used to create a heatmap of genes enriched along the rod versus cone branches (Supplementary Data 4, Fig. 5E). While many of these genes are known as rod- or cone-specific, we identified some novel cone- or rod-enriched genes. In addition to *MPP4* and *CC2D2A*, genes already shown to be enriched in human fetal cones, we identified *GNAI3*, *CA2*, *MAP4*, *MYL4*, *MCF2*, *KIF2A*, and *KIF21A* as cone-enriched, and *PTPRZ1*, *CABP5*, *IRX6*, *B2M*, and *PRUNE2* as rod-enriched (Supplementary Fig. 12) (50). We checked published adult human scRNAseq

data and confirmed significant enrichment of *MAP4*, *MYL4*, *MCF2*, and *KIF2A* in cones, and *CABP5* and *IRX6* in rods ( $p < 0.05$ , one-sided T-test) (60). We performed similar trajectory analyses using adult photoreceptor data to compare the organoid trajectory to *in vivo* photoreceptors (Supplementary Fig. 13) (60). The resulting trajectory separated rods and cones, and the top 100 non-ribosomal differentially expressed genes between the state 1 rods and state 4 cones were used to create a heatmap for comparison to organoid development. 30 genes were differentially expressed in both datasets, with all but *MALAT1*, *TMSB10*, and *EEF1A1* exhibiting the same enrichment pattern. The expression patterns of known markers confirm that our trajectory accurately recapitulates photoreceptor development and validate its utility for analysis of perturbations occurring in NRL null photoreceptors.

### **Reconstruction of the combined WT and L75Pfs trajectory**

After creating a WT trajectory that accurately represented photoreceptor development, we applied the same parameters to create a trajectory of 13,317 combined WT and L75Pfs photoreceptors to elucidate the shift in development resulting from the absence of NRL (Fig. 6A-D). Again, there were few contaminating bipolar cell precursors (254/13,317 cells with *VSX1* or *VSX2* expression) that likely did not affect trajectory reconstruction. The combined trajectory indicated 9 cell states, compared to 3 states of the WT-only trajectory. We sought to characterize these states by their gene expression and gene ontology (GO). After the start of pseudotime with state 1, the first node separated two populations of immature photoreceptors. To characterize the photoreceptors in state 9, we input genes enriched in this state to a GO tool (82). The enriched GO terms included various cell differentiation and cell stress processes (Supplementary Fig. 14). The remaining portions of the trajectory included developing photoreceptors (states 2, 3, and 4), and 4 branches corresponding to 2 rod and 2 cone

cell fates. States 2, 3, and 4 were defined as developing photoreceptors due to expression of *CRX*, *OTX2*, and *RCVRN* and absence of WT cells with substantial rod or cone gene expression patterns (Supplementary Fig. 15B-D). These states have some cells expressing *NRL* or *ARR3*, but the low numbers and level of expression, compared to the more clearly-defined rod and cone populations of states 5, 6, 7, and 8, suggests they are developing photoreceptors (Fig. 6E). Expression of *NR2E3* and *SAG* in WT cells identified states 7 and 8 as rod/rod-like cell fates and *OPN1MW* expression defined states 5 and 6 as cone fates. To differentiate between cone states 5 and 6, we utilized GO analysis on gene sets enriched in each fate (Supplementary Fig. 15E). State 5 cones were enriched for GO terms relating to electron transport chain and guanylate cyclase activity, whereas state 6 cones had enrichment for retinal development and photoreceptor differentiation terms, suggesting that state 6 cones may be less mature than the more metabolically active cones of state 5. Despite apparent differences in maturity and metabolism, cells in these states were combined into a single cone population for downstream analyses due to confidence in their identity as cone photoreceptors. We performed similar analyses on states 7 and 8 to distinguish between the two rod/rod-like populations (Supplementary Fig. 15F). While both populations were enriched for terms related to photoreceptor activity, state 8 cells appear to have stronger rod profiles due to enrichment in rhodopsin signaling terms. As with the cone states, cells of these two rod states were combined into one rod population for downstream analysis. This analysis identified the L75Pfs photoreceptor populations and their WT counterparts, thus allowing for further comparison of mature L75Pfs photoreceptor populations to WT rods and cones.

### **Characterization of L75Pfs S-opsin expressing cells**

Because previous murine studies described *Nrl*<sup>-/-</sup> photoreceptors as possible “cops”, we sought to determine if this would hold for human *NRL* null photoreceptors<sup>3</sup>. To better characterize the L75Pfs photoreceptors, we determined genes differentially expressed compared to WT cells in each photoreceptor subset. Comparison of genes enriched in either WT or L75Pfs cone states (combined states 5 and 6) revealed 184 genes, few of which were rod- or cone-specific genes (Supplementary Data 5). Importantly, nearly all cone-specific genes showed no significant differential expression between WT and L75Pfs cones (Fig. 6F). Exceptions included *ARR3*, *GRK7*, and *OPN1SW*, which were more highly expressed in L75Pfs cells, and *PDE6H*, which showed slight enrichment in WT cells. Lower *OPN1SW* expression in WT cones was expected as ML-cones are the dominant cone subtype in WT organoids (Fig. 2P). The low number of differentially expressed genes and comparable expression levels of most cone genes between WT and L75Pfs cones suggests that this population of L75Pfs cones is essentially normal.

To characterize L75Pfs photoreceptors in the rod/rod-like branches (states 7 and 8), we compared them to both WT rods and WT cones by performing differential gene expression analysis according to the schematic in Fig. 7A (L75Pfs rod-like red cells vs WT rod purple cells; L75Pfs rod-like red cells vs WT cone blue cells). L75Pfs photoreceptors of the rod-like states had high *OPN1SW* expression, while also exhibiting WT rod levels of *OPN1MW* expression and WT cone levels of *NR2E3/SAG* expression (Fig. 7B). In comparing L75Pfs and WT rods/rod-like cells, 397 genes were differentially expressed (Supplementary Data 6), with L75Pfs photoreceptors expressing significantly lower levels of the rod-specific genes *CNGB1*, *GNAT1*, *GNB1*, *GNGT1*, *NR2E3*, *NRL*, *PDE6G*, *ROM1*, and *SAG* than their WT counterparts (Fig. 7C). The expression levels of these rod genes in L75Pfs rod-like cells were comparable to their expression levels in WT cones (Supplementary Fig. 16A). The low expression of these genes compared to

WT rods is likely due to the loss of NRL. In comparing L75Pfs rod-like cells to WT cones, 791 genes were differentially expressed, including many cone-specific genes (Supplementary Data 7). Compared to WT cones, L75Pfs rod-like cells had significantly lower expression of *ARR3*, *CNGB3*, *GNAT2*, *GNB3*, *GNGT2*, *GUCA1C*, *PDE6C*, and *PDE6H* (Fig. 7D). Except for *ARR3* and *PDE6H*, all of these genes were expressed at comparable levels in L75Pfs rod-like cells and WT rods (Supplementary Fig. 16B). Interestingly, L75Pfs rod-like cells also had significantly higher expression of *GNGT1*, a rod transducin also associated with foveal cones (58). The high *OPN1SW* expression, rod levels of expression of cone genes, cone levels of expression of rod genes, and degree of differential gene expression compared to WT rods and cones suggests that L75Pfs rod-like cells are human analogs of "cods".

### **MEF2C as a candidate regulator of cone cell fate**

Because the cod expression pattern is not completely consistent with either rods or cones, the presence of this population suggests that NRL is not the only transcription factor directing rod versus cone photoreceptor fate specification. We postulated that other transcription factor(s) with higher expression in cones than L75Pfs cods could play a previously unappreciated role in regulating cone development. We identified 75 transcription factors of the 791 genes differentially expressed between WT cones and L75Pfs cods, with *MEF2C* as a potential candidate due to its higher expression level in both WT and L75Pfs cones compared to L75Pfs cods and WT rods (Fig. 7E).

Interestingly, *MEF2C* has been shown to act downstream of *Nrl* in mice; however, in our dataset *MEF2C* showed significant enrichment in cone photoreceptors, suggesting a potential difference between human and murine photoreceptor fate determination (83). To determine if *MEF2C* could be involved in human photoreceptor gene regulation, we queried human retinal ATAC-seq data for regions of open chromatin with *MEF2C*

binding sites (78). After identifying 475 genes with MEF2C binding sites, we tested for enrichment of MEF2C-regulated genes in our dataset. 375 genes (80%) were expressed in at least 10 cells in this photoreceptor dataset, a significant enrichment compared to the expected 50% for random genes (Fig. 7F). Furthermore, 34 genes (7.2%) were differentially expressed between L75Pfs cods and WT cone cells, a significant enrichment compared to 4.2% expected for random genes (Fig. 7G). This enrichment in expressed genes and differentially expressed genes suggests a possible role for MEF2C in photoreceptor development, and specifically rod versus cone cell fate specification. Consistent with our transcriptome data, MEF2C protein was detected exclusively in ARR3+ photoreceptors in both WT and L75Pfs retinal organoids at d160 (Fig. 7H, Supplementary Fig. 17A-J). MEF2C expression was also detected in d122 human fetal retina within a single cell layer adjacent to NR2E3+ developing rod nuclei, consistent with cone localization (Supplementary Fig. 17K-N). Strong MEF2C expression was also detected in peripheral adult monkey retina in infrequent cells next to NR2E3+ rod nuclei, also corresponding to cones (Supplementary Fig. 17O-R), and within a line of INL nuclei likely corresponding to Müller glia. Additionally, faint expression was detectable in rod nuclei (Supplementary Fig. 17Q). Furthermore, analysis of published adult human scRNAseq data confirmed enrichment of *MEF2C* expression in cones relative to rods ( $p=0.04489$ , one-sided T-test) (60). This protein localization profile, adult human photoreceptor expression analysis, and enrichment both in expressed genes and differentially expressed genes in our dataset suggests a possible role for *MEF2C* in human cone photoreceptor development or maturation.

## Discussion

We have used an *in vitro* human stem cell-based system to investigate photoreceptor development in *NRL* null human retinal organoids. L75Pfs has been

identified as a null allele, and L75Pfs-derived retinal organoids have a phenotype similar to the phenotype of the *Nrl* null mouse (12, 15, 17). Rods were not detected by immunocytochemistry (Fig. 1 and 2) and the portion of the ONL typically populated by rods in WT organoids instead contained S-opsin<sup>+</sup> photoreceptors. This perturbation of photoreceptor cell fate determination was accompanied by a dramatic shift in the ratio of S- to ML-opsin<sup>+</sup> photoreceptors (Fig. 2). Additionally, we confirmed that this phenotype was due to lack of NRL by reintroducing functional *NRL* and demonstrating restriction of S-opsin expression and promotion of RHO expression in mutant photoreceptors (Fig. 3).

To better understand the identity of the photoreceptor populations that develop in the absence of NRL, we performed scRNAseq to characterize the cell populations of WT organoids compared to L75Pfs organoids. Previous studies have analyzed retinal organoid development using scRNAseq; however, the findings were limited by an inability to resolve cell clusters, the loss of INL cell populations, or incomplete characterization of photoreceptor populations (37, 44, 46). Using transcriptomics, our analyses verified that retinal organoids generate all major neuronal cell types present in *in vivo* retina (Fig. 4). Our findings also enabled comparison of the timeline of retinal organoid and *in vivo* fetal retinal development. Previous fetal retinal bulk RNAseq analysis characterized three “epochs” of retinal development, with photoreceptor development occurring during the third epoch (84). In comparing the timeline of retinal organoid development to that of the fetal retina, the organoids used in this study corresponded to this final epoch. Similar to *in vivo* retinal development, retinal organoids exhibit an early emergence of horizontal and amacrine cells, expression of cone-opsin prior to rhodopsin, and the later development of bipolar cells. Through our analyses we have generated a more comprehensive picture of the transcriptome of retinal organoids and provided a platform to further “stage” *in vitro* retinal organoid development compared to that of *in vivo* fetal retinas (36).

In addition to characterizing retinal organoid development in a WT system, we also provided a comprehensive picture of human photoreceptor development in the absence of NRL. Similar to a recent study characterizing cone photoreceptor development in human retinal organoids in the absence of the transcription factor THRB, we determined how loss of the rod transcription factor, NRL, affects rod and cone photoreceptor genesis (40). While *Nrl* loss has been studied extensively in mice, to our knowledge this work represents the first transcriptomic characterization of human NRL null photoreceptors, and demonstrates similarities and differences between murine and human retinal development (14-18). In both humans and mice, loss of NRL leads to development of an S-opsin+ photoreceptor dominant retina at the expense of rods. Murine *Nrl* null photoreceptors exhibited absent or decreased expression of *Rho*, *Gnat1*, *Nr2e3*, *Rom1*, *Rcvm*, *Gnb1*, and *Cnga1*, consistent with our observations of decreased expression of these genes in human retinal organoids (17, 18). While *Sag* is expressed in murine *Nrl* null photoreceptors, albeit at lower levels, we detected no *SAG* expression in human NRL null photoreceptors (Fig. 6E). Human NRL null photoreceptors also exhibited substantial expression of the rod transducin *GNGT1*, which is not expressed in *Nrl* null mice. Consistent with upregulation of cone-specific genes in murine *Nrl* null photoreceptors, we also detected higher expression of *OPN1SW*, *GNAT2*, *GNGT2*, and *GNB3* in NRL null photoreceptors compared to WT. However, studies of *Nrl* null mice utilized population transcriptomics and thus only characterized the expression pattern of the average *Nrl* null photoreceptor (16). Through single cell analysis, we identified two distinct populations of NRL null photoreceptors, with one population bioinformatically indistinguishable from WT cones and the other representing a rod population with high *OPN1SW* expression but significantly lower expression of other rod- or cone- specific genes. This finding differs from previous studies that characterized *Nrl* null photoreceptors as “normal” S-cones (17, 18). Our model of two distinct *OPN1SW*

expressing populations is compatible with the phenotype of enhanced S-cone syndrome due to the preservation of cone function in concert with retinal degeneration (12). It is possible that preservation of S-cone function stems from the “normal” NRL null S-cone population, whereas the *cod* population may explain the degenerative phenotype. Of note, patients with enhanced S-cone syndrome lack normal retinal architecture, a phenotype not recapitulated in NRL null retinal organoids, and this disorganization may contribute to the degeneration observed *in vivo* (12).

In addition to characterizing photoreceptor populations, the availability of NRL null retinal organoids provided a platform for novel transcription factor discovery. Kim et al. (2016) combined transcriptomics and epigenetics in the context of *Nrl* null mice to identify candidate regulators of photoreceptor cell fate (16). We utilized a similar methodology to identify *MEF2C* as a candidate regulator of cone cell fate specification due to its higher expression in cones and enrichment of differentially expressed genes with MEF2C binding sites. Interestingly, *MEF2C* had been identified through analyses of *Nrl* null mice, but as a transcription factor involved in conferring rod identity (83). These opposing roles may be due to differences in human and murine retinal development, the existence of MEF2C splice variants, or the temporal expression pattern of *MEF2C* during retinogenesis, as Hao et al. (2011) detected *MEF2C* exclusively in mature murine retinas and not during development (83). In both developing organoids and fetal human retina, MEF2C was primarily detected in cones and remained cone-enriched in adult primate retina (Fig. 7H, Supplementary Fig. 17). While our immunocytochemical evidence of MEF2C enrichment in developing cones supports a possible role for MEF2C in cone development, further studies, such as cell type-specific gain- and loss-of function experiments, will be necessary to determine experimentally the possible role of *MEF2C* in cone cell fate specification and/or maturation.

**Table 1: Percent of d170 cells expressing select rod and cone markers and level of expression<sup>1</sup> of these markers showing altered expression of *NR2E3* and *OPN1SW* in L75Pfs organoids.**

*Table 1*

<sup>1</sup>Statistically significant differences are highlighted in yellow.

	% Cells expressing		Average (normalized ) expression level within expression group		Average (normalized) total expression level	
	WT	L75Pfs	WT	L75Pfs	WT	L75Pfs

**Figure 1: Photoreceptors from L75Pfs retinal organoids lack NRL protein expression. A-T)** Confocal images of d100 (stage 2) organoids from a WT line (**A-E**) or 3 individual clonal lines of the L75Pfs mutant (**F-T**) showing photoreceptors immunostained for RCVN (**B, G, L, Q**), CRX (**C, H, M, R**), or NRL (**D, I, N, S**). (**A, F, K, and P**: nuclei (blue); **E, J, O** merge in **T**). Scale bars = 50 microns.

*Figure 1*

**Figure 2: L75Pfs retinal organoids display an overabundance of S-opsin expressing cells at the expense of rods compared to WT organoids. A-B)** Confocal images from stage 3 organoids (i.e., presence of photoreceptor outer segments) showing a single layer of cones with few S-cones (green) in WT organoids (**A**) versus an abundance of S-cones (green) distributed throughout the ONL in L75Pfs organoids (**B**). ML-cones are shown in orange. Scale bars = 25 microns. **C-N)** Photoreceptor characterization of WT and L75Pfs retinal organoids. Bright field (**C, I**) and confocal (**D-H** and **J-N**) images showing S-opsin+/ARR3+ cones (**K, L**) distributed throughout the ONL of L75P(fs) organoids that do not express the rod marker NR2E3 (**M**) (a transcription factor whose expression is controlled by NRL). This finding is in contrast to WT organoids that display ordered expression of cones (**E, F**) along the outermost ONL with a multicellular layer of NR2E3+ rod nuclei (**G**) internal to the cone layer, as well as an overall low number of S-opsin+ (**E**) cones. Scale bars: **C, I** = 250 microns; **D-H** and **J-N** = 25 microns. **O-P)** Quantification of photoreceptors in confocal images of stage 3 organoids from 3 WT lines and 3 L75Pfs clones. **O-P)** Quantification of photoreceptors in confocal images of stage 3 organoids from 3 WT lines and 3 L75Pfs clones. **O)** NR2E3+ rod and ARR3+ cone abundance as a percentage of total nuclei in the ONL: 15 images from 5 organoids per line or clone were counted. **P)** ML- and S-cone abundance as a percentage of total ARR3+ cones in the ONL: 11 WT images from 4 organoids per line and 15 L75Pfs images from 5 organoids per clone were counted. **Q)** RT-qPCR from stage 2-3 organoids showing a reduction in rod transcripts and an increase in S-opsin transcripts in L75Pfs organoids relative to WT organoids.  $p < 0.005$ , Mann-Whitney test.

*Figure 2*

**Figure 3: RHO expression is found in L75Pfs organoids following viral transduction with an *NRL*-expression cassette. A-H)** Confocal images from L75Pfs organoids transduced with a control lentivirus carrying a pgkGFP expression cassette. GFP (**C**) was found in ARR3+ (**B**) cones; NRL (**G**) was not detected, and S-opsin+ cones (**F**) were localized throughout the ONL and no RHO (**K**) expression was detected, as expected in the absence of ectopic WT NRL expression. **M-X)** Confocal images from L75Pfs organoids transduced with lentivirus carrying a pgkNRL expression cassette reveal patches of NRL expression within the ONL (**O** and **S**) and no NRL co-expression with S-opsin (**N** and **R**; merges in **P** and **T**). However, ectopically expressed NRL does co-express with RHO (**Q**; merge in **T**), a rod marker that was never present in control transduced L75Pfs organoids. In pgkNRL-transduced organoids, RHO (**W**) did not co-localize with the cone marker ARR3 (**V**; merge in **X**). Scale bars = 25 microns.

*Figure 3*

**Figure 4: Identification and characterization of cell populations present in WT and L75Pfs retinal organoids by scRNAseq. A)** tSNE plot showing cell populations present in all d100 organoids. **B)** Expression of *NR2E3* in WT (top) compared to L75Pfs (bottom) cells, showing that nearly all expression is in WT cells. **C)** tSNE plot showing cell populations present in all d170 organoids. **D)** Scatter plot of *OPN1SW* and *OPN1MW* expression at d170 indicating 6 co-expressing cells. **E)** Scatter plot showing the number of UMIs and genes expressed by the 6 co-expressing cells from D. **F)** Violin plots showing specific enrichment of novel cone marker genes across WT ML-cones, ML/S-cones, and S-cones. **G and H)** Heatmap of genes differentially expressed in d170 rod (**G**) and S-cone (**H**) clusters between WT and L75Pfs cells. **I)** Comparison of expression of *OPN1SW*, *OPN1MW*, and *NR2E3* by cell population of WT and L75Pfs organoids, and total expression of *OPN1SW*, *OPN1MW*, and *NR2E3* within all WT and L75Pfs cells.

**Figure 4**

**Figure 5: Reconstruction of a WT photoreceptor developmental trajectory. A-C)**

Trajectory of 5144 WT photoreceptors colored by state (A), pseudotime (B), and age (C).

(D) Expression of photoreceptor markers used to distinguish the identity of each branch of the trajectory.

(E) Heatmap of the top 100 non-ribosomal differentially expressed genes at the node separating rods and cones.

Genes are hierarchically clustered into 4 clusters based on expression pattern. The center of the heatmap is the

beginning of pseudotime, with cell maturity moving horizontally to the left (cones) and

right (rods).

right (rods).

*Figure 5*

**Figure 6: Combined analysis of WT and L75Pfs photoreceptor populations. A-D)** Trajectory of combined WT and L75Pfs photoreceptors colored by state (A), genotype (B), pseudotime (C), or age (D). **E)** Expression of rod and cone marker genes by state, with L75Pfs cell populations on the left and WT cell populations on the right. WT expression of *NR2E3* and *SAG* was used to assign states 7 and 8 as rods, and expression of *OPN1MW* to assign states 5 and 6 as cones. **F)** Expression levels of cone markers in states 5 and 6 by genotype, with the position of the largest dot indicating the average level for each marker. All genes are expressed at comparable levels except *ARR3*, *GRK7*, *OPN1SW*, and *PDE6H*.

Figure 6

**Figure 7: Comparative analysis of L75Pfs photoreceptors identifies 2 populations of S-opsin expressing photoreceptors, with one population having gene expression inconsistent with WT S-cones, and identification of MEF2C as a candidate regulator of cone cell fate specification. A)** Plot depicting the differential expression analysis. Gene expression in the cells highlighted in red (L75Pfs rod-like cells) was separately compared to expression in the cells highlighted in blue (WT cones) and the cells highlighted in purple (WT rods). **B)** Expression levels of *NR2E3*, *OPN1MW*, *OPN1SW*, and *SAG* across the 3 cell groups (red, blue, and purple) used for differential analysis. **C-D)** Expression levels of rod- and cone-specific genes differentially expressed between L75Pfs rod-like cells and WT rods (**C**), or WT cones (**D**). The position of the largest dots indicate average gene expression levels for **B-D**. **E)** Expression level of *MEF2C* in cells in the cone states (5 and 6) on the left versus the rod states (7 and 8) on the right, with cells colored by genotype (black = L75Pfs, teal = WT). **F-G)** Percentage of *MEF2C* regulated genes expressed in a minimum of 10 cells (**F**) and differentially expressed between the red (L75Pfs rod-like cells) and blue (WT cones) groups (**G**) versus random genes. **H)** Confocal images demonstrating MEF2C (green) co-expression with ARR3 (purple) in cone photoreceptors of WT (left) and L75Pfs (right) organoids at d160. NR2E3+ nuclei (red) are present in WT but not in L75Pfs organoids. Scale bar = 10 microns.

**Supplementary Table 2: Genes differentially expressed between WT and L75Pfs cells at d170.** Differential expression analysis was performed within each cluster and only genes with a statistically significant Bonferroni corrected p value and average natural log fold change > 0.5 were included. The “genotype” column indicates in which genotype each gene is enriched.

### **Chapter 3: Modeling LCA in human stem cell derived retinal organoids**

#### **Characterization of CRB1 and RPGRIP1 KO human retinal organoid models of LCA and identification of ER stress as a common degenerative pathway**

##### **Abstract**

Photoreceptor loss is a largely untreatable cause of blindness, and LCA is the most severe form of retinal degeneration, with patients being severely visually impaired within the first year of life. There are over 20 known causative genes, and identification of degenerative pathways shared across different genetic models could provide targets for therapeutic development. To address this need, we generated retinal organoid models of LCA due to CRB1 or RPGRIP1 loss and characterized these models histologically and transcriptomically over a time course of development. Mutant organoids exhibited different histological aberrations, with CRB1 KO organoids developing a thickened ONL and aberrant rhodopsin expression pattern, while RPGRIP1 KO organoids suffered ONL thinning and an absence of outer segment discs. Despite histological differences, we report convergence upon DDIT3 induction and ER stress as a common degenerative pathway across these genetically different LCA models, and this pathway may provide therapeutic targets for retinal degeneration treatment.

##### **Introduction**

Normal visual perception begins with a series of signal transduction events in the neural retina, with photoreceptors detecting photons of lights and ultimately transmitting this signal to the brain (1, 2). Vision can be impaired by various genetic and environmental insults, and disorders of the retina typically result from degeneration of retinal ganglion cells, retinal pigmented epithelium, and photoreceptors. Inherited retinal

degeneration is an important cause of irreversible vision loss, with over 200 genes known to cause this heterogeneous set of disorders (RetNet). Photoreceptor cell death can result from a variety of diseases, including Macular Degeneration, Retinitis Pigmentosa, and Leber Congenital Amaurosis (LCA) (85). While great advances in gene therapy have recently been made for the treatment of LCA due to RPE65 mutation, the other forms of inherited retinal degeneration remain largely untreatable (27). Better understanding of the complex gene expression patterns directing photoreceptor degeneration could elucidate the mechanisms of photoreceptor death and identify potential therapeutic targets.

LCA is the most severe form of inherited retinal degeneration, with patients exhibiting blindness or severe visual impairment within the first year of life (9, 10). There are over 20 genes known to cause LCA, and they manifest as a variety of inheritance patterns and phenotypes (9). LCA can exhibit autosomal dominant or recessive inheritance patterns, affect either photoreceptor or retinal pigmented epithelium function, and photoreceptor death can occur as either rod-cone or cone-rod dystrophies (9, 10). Mouse models have been useful to study the degenerative phenotype of different forms of LCA, including LCA due to mutation of *Aipl1*, *Crb1*, *Gucy2e*, *Nmnat1*, *Rpe65*, *Lrat*, and *Rpgrip1* (19-21, 24-26). While murine studies have provided important insights into the pathology of LCA, human models of LCA could facilitate identification of new therapeutic targets. Importantly, due to the heterogeneity of LCA and other inherited retinal degenerations, mutation and gene independent treatment options could be effective across many subsets of patients.

Recently, stem cell-derived retinal organoid culture has become a well-established system for modeling retinal development and disease in a human system (22, 23, 36-51, 86). Retinal organoids have been shown to provide valuable insights into both development and degeneration, including models of retinal disease due to

mutations in NRL, CEP290, RPGR, CRB1, and AIPL1 (22, 23, 38, 47, 86). In addition to advances in tissue culture systems in studying retinal disease, single cell RNA sequencing (scRNAseq) has proven powerful across many retinal development and degeneration models (37, 44, 46, 50, 54-60). scRNAseq has enabled elucidation of the critical gene expression alterations occurring in both murine and human retinal development, as well as disease. We have previously shown the utility of combining scRNAseq and retinal organoids to gain insights into another form of inherited retinal degeneration, Enhanced S Cone Syndrome (86).

In this study, we utilized a similar methodology to characterize photoreceptor degeneration in two human models of LCA. We used CRISPR/Cas9 genome engineering to generate human induced pluripotent stem cell (iPSC) lines lacking either functional CRB1 or RPGRIP1, genes known to harbor null alleles causing autosomal recessive forms of LCA, and differentiated these cells into retinal organoids to model a time course of LCA (87, 88). Over 6 time points from days 70 to days 225, we have performed immunohistochemistry (IHC) and scRNAseq to identify both transcriptional and histological alterations occurring over disease progression. We have identified distinct histological aberrations in both knockouts (KO's), as well as induction of DNA Damage Inducible Transcript 3 (DDIT3) and endoplasmic reticulum stress as a common degenerative pathway. Our identification of a shared photoreceptor cell stress pathway may provide targets for therapeutic intervention in the treatment of LCA and possibly other diseases of photoreceptor degeneration.

## **Methods**

### **Cell and retinal organoid culture**

EP1 stem cells were grown in mTeSR1 (Stem cell tech 05850) on matrigel (BD Biosciences 354230) coated plates and maintained by passaging with accutase (Sigma

A6964-100ml). After passaging cells were plated in mTesr with blebbistatin (Sigma B0560-1mg). Organoids were differentiated according to Wahlin et al 2017. Stem cells were dissociated to single cells then plated at 3000 cells per well in 96 well U-bottom plates in mTesr with 5  $\mu$ M blebbistatin. On day 1 organoids were fed BE6.2 media (10 mL E6 stock [100 mL water, 97 mg insulin (Roche 11376497001), 53.5 mg holo-transferrin (Sigma T0665-500MG), 320 mg L-ascorbic acid (Sigma A8960-5G), 5  $\mu$ L of 14 mg/mL sodium selenite (Sigma S5261-10G)], 5 mL B27 without vitamin A (Gibco 12587010), 2.5 mL Glutamax (Gibco 16140071), 2.5 mL MEM NEAA (Gibco 11140-050), 2.5 mL sodium pyruvate (Gibco 11360-070), 1 mL 219 g/L NaCl, DMEM (Gibco to 250 mL) plus 2% v/v matrigel and 3  $\mu$ M Wnt inhibitor (EMD Millipore 681669). On days 2-3 organoids were fed with BE6.2 plus 1% v/v matrigel and 3  $\mu$ M Wnt inhibitor, then 50% media exchange with BE6.2 plus 1% v/v and 3  $\mu$ M Wnt inhibitor on days 4-7. 50% exchange was continued on days 8-9 with only BE6.2. On day 10 organoids were transferred to 10 cm dishes and fed with BE6.2 plus 100 nM SAG (EMD Millipore 364590-63-6) until day 12. Optic vesicles were manually excised from organoids using tungsten needles from days 10-14. Organoids were fed with LTR medium (125 mL F12 (Gibco 11765), 50 mL FBS (Gibco 16140071), 10 mL B27 (Gibco 17504044), 5 mL Glutamax, 5 mL MEM NEAA, 5 mL sodium pyruvate, 500  $\mu$ L 1M taurine (Sigma T-8691), and DMEM up to 500 mL) plus 100 nM SAG until day 18. Organoids were fed with only LTR medium on days 18-19. From days 20-27, organoids were fed with LTR plus 500 nM retinoic acid (Sigma R2625-50mg), and days 28-42 with LTR plus 500 nM retinoic acid and 10  $\mu$ M DAPT (Calbiochem 565770). Organoids were fed with LTR plus 500 nM retinoic acid until day 120, then fed with only LTR.

### **CRISPR gene editing**

EP1 stem cells were dissociated and plated in at ~50,000 cells per well in a 24 well plate with mTeSR plus blebbistatin. The following day, transfection was performed by applying a mixture of 50 uL OptiMEM (Thermofisher 31985062), 2 uL Lipofectamine Stem (Thermofisher STEM00015), and 350-500 ng plasmid containing the gRNA, Cas9 gene, and puromycin resistance cassette. Cells were treated with 0.9 ug/uL puromycin (Sigma P8833) ~40 hours after transfection to select for cells that had taken up the guide plasmid. Cells were then passaged, plated as single cells, and colonies were screened for loss of the wild type allele using HpyAV (NEB R0621S) for RPGRIP1 and Taq<sup>a</sup>1 (NEB R0149S) or MseI (NEB R0525S) for CRB1. Clones containing mutations were sanger sequenced to determine the mutated sequence. Genomic integrity after gene editing was confirmed by karyotyping (KaryoStat, Thermofisher).

### **Fixation and immunohistochemistry**

Organoids were fixed on ice in 4% PFA (Electron Microscopy Sciences 15710) in 0.1 M PB-5% sucrose for 25 minutes then immersed in 6.75% sucrose-PBS for 1 hour, 12.5% sucrose-PBS for 1 hour, 25% sucrose-PBS overnight, and 2:1 25% sucrose-PBS/OCT (Tissue-Tek 4583) for one hour. Frozen 10 um sections were mounted on Superfrost plus slides (Thermofisher) and stored at -80. Sections were blocked in PBS with 0.5% Triton X-100 (Sigma 10789704001) and 10% normal donkey serum (Sigma D9663). Primary antibodies were incubated overnight at 4 degrees in PBS with 2% normal donkey serum and 0.15% Triton X-100. The list of primary antibodies can be found in Supplementary Table 8. Secondary antibodies (Invitrogen, 1:1000) were incubated for 1.5-2 hours at room temperature in PBS with 2% normal donkey serum. Antibody conjugations to distinguish between primary antibodies of the same species were performed using APEX Antibody Labeling Kits (Invitrogen).

### **Imaging and quantification**

Images were taken using either an EVOS microscope or Zeiss LSM 510 confocal. Expression of DDIT3 and RCVRN in confocal images were quantified by total pixel intensity and pixel area of the maximum intensity Z projection. Nested ANOVAs were performed using sections (4-6 per organoid) nested within biological replicates (3 per genotype).

### **Electron microscopy**

Organoids were fixed in cold 2.5% glutaraldehyde/2% PFA in 0.1N cacodylate buffer (pH 7.3), post fixed in cold 1% osmium tetroxide, dehydrated using a graded series of EtOH and embedded in LX112 resin (Ladd Research Industries, Williston, VT). Ultra-thin sections (68nm) were cut on a Leica UC7 ultramicrotome and stained with uranyl acetate and lead citrate and imaged using transmission electron microscopy (Hitachi H7600).

### **Single cell dissociation and capture**

Organoids were individually dissociated to single cells for up to 2 hours with 200  $\mu$ L of papain solution containing 700  $\mu$ L water, 100  $\mu$ L cysteine (6 mg/mL, Sigma W326305), 100  $\mu$ L EDTA (10mM, Corning 46-034-CI), 10  $\mu$ L BME (60 mM, Sigma M6250), papain to 1 mg/mL (Worthington LS003126), and 5  $\mu$ L DNase (Roche 04716728001). Dissociations were quenched with media containing 10% FBS plus 5  $\mu$ L DNase. Dissociated cells were applied to a cell strainer, washed with HBSS, and resuspended at 120,000 cells per mL in HBSS plus 1% BSA (10 mg/mL). Single cells were captured with dropseq beads via a home made Dropseq platform and beads were processed according to the published Dropseq protocol (Macosko et al 2015). Multiplexed libraries were sequenced on the Illumina NovaSeq.

## **Bioinformatics**

Fastq files were processed according to the Dropseq cookbook to extract digital expression matrices (57). Expression matrices were read into R and analyzed using the Seurat v3 R package (89). Cells with greater than 5000 UMIs, less than 200 genes, or greater than 15% mitochondrial content were excluded from the analysis. The WT dataset was merged with either the RPGRIP1 KO dataset or the CRB1 KO dataset by identifying integration anchors with which to integrate the datasets. Differential gene expression within each identified cell population was performed using the fit models function in the Monocle3 R package to identify genes differentially expressed based on genotype (90). For non-photoreceptor populations, a less stringent threshold of 3 cells expressing each gene tested was used for differential gene expression. Photoreceptor populations were extracted from WT, RPGRIP1 KO, and CRB1 KO datasets and read into the Monocle3 R package and analyzed separately as all rods and all cones. Differential gene expression was performed using the fit models function to identify genes expressed in at least 10 cells that were differentially expressed based on genotype and age. These genes were then organized into modules of covarying genes to track how expression of each module varied across time in each genotype.

## **Results**

### **Generation and histological characterization of LCA organoids**

CRISPR/Cas9 was used to perform gene editing via non-homologous end joining on a previously characterized iPSC line, EP1 (49). Compound heterozygotes were generated for both CRB1 and RPGRIP1 and karyotypes were confirmed to be normal by karyostat (Supplementary Fig. 1A-D). CRB1 KO was confirmed by IHC, with only WT organoids exhibiting CRB1 expression along the outer limiting membrane

(Supplementary Fig. 1E). We then sought to characterize possible alterations to the outer nuclear layer (ONL) over a time course of development in WT and KO organoids. Organoids were stained for nuclei and CRX expression at days 90, 120, 150, 190, and 225 and the width of the CRX+ ONL was measured relative to the nuclei dense, organized retinal region of the organoid (Fig. 1A-O). In comparing CRB1 KO (Fig. 1A-E) to WT (Fig. 1F-J) organoids, the ONL thickness was comparable across most time points. However, at day 225, CRB1 organoids exhibited ONL thickening relative to WT, similar to that observed in CRB1 KO LCA patients (Fig. 1E and J) (91). Unlike most retinal degenerations where the ONL thins over time, patients with LCA due to CRB1 loss demonstrate thick, disorganized retinas (91). This thickening at day 225 *in vitro* was statistically significant, with quantification of CRB1 KO versus WT ONL thickness shown in Figure 1P (Wilcoxon Rank Sum Test,  $p=0.05$ ). In comparing RPGRIP1 KO (Fig. 1K-O) to WT (Fig. 1F-J) organoids, the ONL thickness was comparable at the early time points, but showed ONL thinning at later time points. Quantification showed significant ONL thinning at day 150, and increased thinning at days 190 and 225. At day 225, the ONL comprised ~45% of the optic vesicle thickness in the WT organoids, compared to ~30% for RPGRIP1 KO (Wilcoxon Rank Sum Test,  $p=0.05$ ) (Fig. 1Q). Of note, the difference at day 150 was predominantly driven by one RPGRIP1 KO replicate, while all replicates at days 190 and 225 had consistently thinner ONL's compared to WT. This dramatic loss of ONL thickness over time indicated that RPGRIP1 KO photoreceptors were dying as the organoids matured.

After characterizing gross ONL dynamics over time, we performed histological characterization in mature, opsin-expressing rods and cones via IHC staining for RCVRN, RHO, and ML-opsin in day 225 sections. While overall organization of RPGRIP1 KO opsin-expressing photoreceptors appeared comparable to WT (Supplementary Fig. 2A-H), CRB1 KO organoids exhibited a striking RHO+ rod

phenotype (Fig. 1, WT in R-U, CRB1 KO in V-Y). In all three CRB1 KO d225 organoids imaged, RHO expressing rods were not present adjacent to ML-opsin+ cones, rather disorganized patches of RHO expression were detectable in the most interior part of the ONL. Additionally, these RHO+ rods lacked apparent outer segment-like projections. Because of the role of CRB1 in maintaining adherens junctions, it is possible that mature photoreceptors lose their ability to maintain cell-cell adhesion, causing their abnormal localization within the ONL (91, 92). This localization could prevent proper interactions with bipolar cells to transmit signals or improperly localize opsins and thus prevent photon detection, either of which could contribute to visual loss for LCA patients. While organization of RPGRIP1 KO organoids appeared comparable to WT, photoreceptor morphology did not appear normal (Supplementary Fig. 2A-H). Opsin staining localized primarily to cell bodies and little staining was observed in outer segments. We sought to characterize possible defects in RPGRIP1 KO photoreceptor morphology, as RPGRIP1 is thought to interact with RPGR to support outer segments (93). Additionally, a similar study of RPGR KO organoids identified various morphological aberrations in outer segment morphology. Because of the close interactions between RPGR and RPGRIP1, as well as the opsin staining in day 225 photoreceptor cell bodies, we postulated that the RPGRIP1 KO organoids may also produce abnormal outer segments (38). We performed electron microscopy on WT and RPGRIP1 KO organoids at day 245. All 3 WT organoids imaged had evidence of discs in the outer segments, while 0/3 RPGRIP1 organoids had produced discs (Fig. 1Z). While discs were absent in RPGRIP1 KO photoreceptors, gross outer segment morphology appeared comparable to WT. This data provides evidence that disc morphogenesis does not occur in the absence of RPGRIP1 *in vitro*, which may contribute to vision loss suffered by LCA patients lacking RPGRIP1. Lack of disc morphogenesis may prevent proper localization of opsins and

other critical phototransduction proteins in the outer segments, thus severely limiting ability to detect and respond to light.

### **scRNAseq characterization of LCA organoids**

To gain further insights into the molecular aberrations occurring in the absence of CRB1 or RPGRIP1, we performed scRNAseq via Dropseq over days 70, 90, 120, 150, 190, and 225 (57). Across all 6 time points 20,849 cells were captured from WT organoids, 31,138 from CRB1 KO, and 36,067 from RPGRIP1 KO. Each KO dataset was integrated with WT and cells were clustered using UMAP in Seurat (89). All stereotypical cell populations were present in each genotype, including neural progenitor cells, retinal progenitor cells, retinal ganglion cells, horizontal cells, amacrine cells, bipolar cells, retinal pigmented epithelium, muller glia, rods, and cones (Fig. 2A-B, Supplementary Fig. 3 and 4). We also identified an unknown cluster expressing some ciliary margin genes (Supplementary Fig. 5A-B). The distribution of mitochondrial gene content, number of genes captured, and number of transcripts captured confirmed that these features were not driving clustering (Supplementary Fig. 6A-F). For each cell population, we performed differential gene expression tests using Monocle3 to identify genes differentially expressed between each KO and WT (90). As expected, most cell types had very few genes differentially expressed between WT and KO. In comparing CRB1 KO and RPGRIP1 KO to WT, amacrine cells, horizontal cells, bipolar cells, retinal pigmented epithelium, and the unknown cluster all had less than 35 genes differentially expressed (Supplementary Tables 1 and 2). The lack of many differentially expressed genes in these non-photoreceptor cell types serves as an important internal control for batch effects. While retinal ganglion cells, retinal progenitor cells, and neural progenitor cells had >70 genes differentially expressed between KO and WT, gene ontology analysis did not reveal any clear biologically significant pathways from the differentially

expressed gene sets (Supplementary Tables 3 and 4). Of non-photoreceptor populations, muller glia were the most different in WT versus KO organoids, with 879 genes and 788 genes differentially expressed between CRB1 KO and RPGRIP1 KO muller glia compared to WT, respectively. This degree of differential gene expression was unsurprising considering the role of muller glia in retinal degeneration and photoreceptor cell death (94). We performed gene ontology analysis on gene sets enriched in KO muller glia compared to WT (82). Interestingly, both RPGRIP1 KO and CRB1 KO muller glia were highly enriched for terms related to chaperone mediated autophagy (CMA) (Table 1). CMA has been shown to be an important pathway in both photoreceptors and retinal pigmented epithelium during retinal degeneration, as dysregulation of protein and organelle homeostasis contributes to cell stress (95-97). To our knowledge, there have been no reports of CMA dysregulation in muller glia of degenerating retinas. While reactive gliosis of muller glia is known to contribute to retinal degeneration, further investigation into the role of muller glia CMA could provide additional insights into the extent of muller glia involvement in degenerative phenotypes (94).

We then sought to identify and characterize transcriptomic alterations in photoreceptor populations over the time course of differentiation. Photoreceptors of all 3 genotypes were subsetted and reclustered in Monocle3 (Fig. 2C, Supplementary Fig. 7) (90). We then performed differential gene expression tests based on age and genotype separately for rods and cones. 534 and 789 genes were differentially expressed in the rod and cone populations, respectively (Supplementary Table 5). Of note, the number of genes differentially expressed for the photoreceptor populations is lower than that of the muller glia as more stringent thresholds were set for photoreceptors to limit the effect of possible uninteresting sources of variation and batch effects (minimum 10 cells expressed for photoreceptor genes compared to 3 for non-photoreceptors). These

genes were then clustered into modules of differentially expressed genes to create a heatmap of expression level of each module in each group of cells, with cell groups designated with the genotype and time point. For differentially expressed genes in cones, modules 1, 4, 8, 9, 12, 13, 15, and 16 were enriched at the earlier time points, whereas modules 2, 3, 5, 6, 7, 10, 11, 14, and 17 were enriched at the later time points (Fig. 2D). As expected, the modules expressed highly at the later time points were enriched for GO terms related to more mature photoreceptor characteristics such as guanylate cyclase activity and cone development, while the modules enriched in the less mature cells corresponded to GO terms not specific to photoreceptor function (Supplementary Table 6). For rods, modules 2, 3, 4, 6, 8, 9, and 10 were enriched at earlier time points, while modules 1, 5, 7, and 13 were enriched at later time points (Fig. 2E). Modules 11 and 12 did not seem to exhibit a clear pattern over age. GO analysis for rods revealed similar results to cones, with modules expressed in mature rods highly enriched for GO terms related to rhodopsin signaling and guanylate cyclase activity. These time point-dependent modules confirmed expected transitions towards photoreceptor-specific functions as organoid photoreceptors matured.

We then sought to identify modules that were enriched based on genotype using a minimum expression difference of 0.5 between WT and KO photoreceptors. For cones, modules 12 and 13 were enriched in WT and depleted in both KO's (Fig. 3A). The genes in these modules were enriched for the mitochondrial ATP synthesis coupled electron transport GO term ( $p$  value =  $3.93e-7$ , fold enrichment = 16.16), indicating that the WT cones may be more metabolically active, whereas the KO cones seem to be downregulating energy production. Modules 9 and 14 were enriched in both CRB1 KO and RPGRIP1 KO cones compared to WT, which corresponded to GO terms related to the unfolded protein response, cell stress, and autophagy (Supplementary Table 7). Modules 9 and 14 included many heat shock genes, and interestingly the endoplasmic

reticulum (ER) stress induced pro-apoptotic gene DDIT3 (98). The enrichment of these genes in both KO's compared to WT cones indicated that ER stress may be involved in photoreceptor degeneration. Additionally, the most highly enriched GO term related to NOD2 signaling, a pathway that has been shown to mediate ER stress (99). Taken together, these results suggest that ER stress may be an important degenerative pathway in KO cones. In rods, modules 2, 8, 9, and 12 were enriched in WT compared to KO photoreceptors (Fig. 3B). These genes corresponded primarily to GO terms related to translational and ribosomal processes (Supplementary Table 7). Modules 1, 3, 5, 7, 11, and 13 were enriched in KO rods. While these modules also included many heat shock genes and DDIT3, the enriched GO terms were predominantly related to rhodopsin signaling and photoreceptor development (Supplementary Table 7), possibly due to lower capture of WT rods at later time points. The similarity between GO terms corresponding to WT rod enriched modules and early age dependent modules provides additional support for the effect of maturity distributions on genotype dependent modules in rods.

To determine if DDIT3 and other cell death-related genes were enriched in KO photoreceptors regardless of age distributions, we next regressed out the effect of age prior to differential gene expression analysis. Using a list of cell death related genes obtained from Qiagen, we performed differential gene tests between KO and WT rods and cones (Table 2). DDIT3 was significantly enriched in RPGRIP1 KO rods, CRB1 KO rods, and CRB1 KO cones, with average expression level and percent of cells expressing DDIT3 shown in Figure 3C-D. Many genes enriched in WT compared to KO were protective against stress and cell death, including BAG1, DAD1, GSTP1, PRDX5. Interestingly, GSTP1, the only gene consistently downregulated compared to WT across all photoreceptor groups, has been shown to be protective against neurotoxic conditions (100). Altogether, the single cell transcriptomics and differential gene expression

analysis suggest that induction of DDIT3 and ER stress may serve as a common pathway underlying the photoreceptor degeneration seen with RPGRIP1 and CRB1 associated LCA.

### **ER stress in LCA organoids**

Next we sought to validate DDIT3 enrichment at the protein level by performing IHC for DDIT3 and RCVRN and comparing both the relative area and intensity of DDIT3 signal to RCVRN over all time points. At day 150, the area and intensity of DDIT3 expression were significantly enriched in CRB1 KO organoids, but not RPGRIP1 KO organoids, relative to WT (Fig. 4A-K) (Nested ANOVA,  $p < 0.05$ ). Of note, RPGRIP1 KO replicate 1 was excluded from the area analysis due to significant inter-replicate variation. Interestingly, this outlier organoid was also the main driver of significant ONL thinning relative to WT at day 150. At day 190, both KO's exhibited significant enrichment of both area and intensity of DDIT3 expression relative to WT (Fig. 4L-V) (Nested ANOVA,  $p < 0.05$ ). While both KO's appear to be converging on a shared ER stress response and induction of DDIT3, the duration and onset differs between KO's. CRB1 KO organoids appear to activate DDIT3 earlier and maintain ER stress over a longer time range, whereas RPGRIP1 KO organoids exhibited a rapid spike in DDIT3 expression and ER stress at day 190. It is possible that these differences in onset and duration are due to the specific roles and temporal expression patterns of CRB1 and RPGRIP1 in photoreceptor development and maturation. Despite these differences, the convergence upon ER stress provides a possible degenerative pathway to target for therapeutic intervention. Examination of other LCA models for evidence of ER stress could provide further support for this pathway as a therapeutic target.

## Discussion

In this study, we have characterized the histological and transcriptomic changes occurring over development in two genetically distinct retinal organoid models of LCA, and identified DDIT3 induction and ER stress as a common degenerative pathway across both models. In the case of the CRB1 KO organoids, we report thickening of the ONL and aberrant ONL organization at day 225, with RHO expression occurring in patches in the most internal region of the ONL. These findings partially recapitulate the Crb1 KO mouse model, *rd8*, in which mice exhibit retinal disorganization (92). Homozygous *rd8* mice suffer structural alterations due to the loss of adherens junctions, and this loss could also explain both the abnormal localization of RHO+ rods within the ONL and patchy expression of RHO+ within the photoreceptors (92). Similarly, a second Crb1 KO mouse model also recapitulates the phenotype of photoreceptor displacement due to the loss of adhesion between photoreceptors in the ONL (92). The presence of this phenotype in both murine models of Crb1 loss and our retinal organoid model supports the role of CRB1 in maintaining organization of the ONL in both mice and humans. While organization is disrupted in both murine and human models, *rd8* mice also suffer rosette formation and thinning of the ONL, findings not recapitulated in the CRB1 KO organoids described here (92, 101). Despite the absence of these phenotypes in CRB1 KO organoids, these observations were reported for aging mice whose time course of degeneration was likely beyond the window of organoid development in this study. It is possible that organoids at a later time point more consistent with aged mice could recapitulate these phenotypes *in vitro*. Additionally, both murine and other human organoid models of retinitis pigmentosa due to CRB1 mutation report loss of outer limiting membrane integrity (47, 92, 101). The CRB1 KO organoids described here differ from previously described retinal organoids differentiated from patient iPSC lines with CRB1 mutations in that we did not observe disruptions to

outer limiting membrane integrity (47). However, previous organoid models of CRB1 mutation produced a variant protein, as opposed to total loss of CRB1 protein in the organoids described here, which could explain the differences in phenotype (47). While the CRB1 KO organoids displayed some differences to other *in vitro* human models and *in vivo* mouse models, the retinal thickening and abnormal organization are consistent with observations of LCA patients with CRB1 loss (91, 92).

In the case of the RPGRIP1 KO organoids, we report dramatic thinning of the ONL over time, opsin expression incorrectly localizing primarily to photoreceptor cell bodies, and absence of outer segment discs. ONL thinning due to photoreceptor loss and abnormal pattern of opsin staining are both phenotypes also present in two mouse models of RPGRIP1 loss (102, 103). In both the *Rpgrip1*<sup>tm1Tili</sup> and *Rpgrip1*<sup>nmf247</sup> mouse models, opsins are mislocalized to cell bodies rather than photoreceptor outer segments (102, 103). This is consistent with the RPGRIP1 KO organoid phenotype, and improper localization of opsins in both murine and human models supports the proposed role of RPGRIP1 in trafficking proteins to the outer segments. While ONL thinning and mislocalization of opsins are phenotypes consistent with mouse models of *Rpgrip1* loss, the outer segment phenotype is different from the murine phenotypes. This may be due to the different cellular localization of RPGRIP1 in humans and mice, with human RPGRIP1 localizing to outer segments and murine *Rpgrip1* localizing to the connecting cilium (102-104). In the *Rpgrip1*<sup>tm1Tili</sup> mouse, disc morphogenesis does occur, however discs appear swollen with a larger than normal diameter (103). This is in contrast to the *Rpgrip1*<sup>nmf247</sup> mouse, which exhibits a more severe phenotype in which photoreceptors rarely develop outer segments (102). The RPGRIP1 KO organoids described here differ from both of these murine phenotypes, with an intermediate severity of outer segment formation but absence of discs. Because genetic background affects the outer segment phenotype in *Rpgrip1* KO mice, it is possible that other human models of RPGRIP1 loss

may also exhibit a range of severity with regard to outer segments and disc morphogenesis. Because RPGRIP1 is thought to interact with RPGR to facilitate ciliary transport in photoreceptors, the phenotypes associated with RPGRIP1 loss could be expected to overlap with RPGR phenotypes (104). A previous study of retinal organoids with RPGR loss reported abnormal photoreceptor morphology, as well as a decrease in photoreceptor cell number relative to control organoids (38). These findings are consistent with the RPGRIP1 KO organoid phenotypes reported here. While both RPGR and RPGRIP1 KO organoids exhibit photoreceptor loss and abnormal morphology, the morphological changes differ. RPGR KO organoids exhibited RHO staining in outer segments, but abnormal outer segment morphology, whereas RPGRIP1 KO organoids had primarily RHO expression in the cell body portion of the photoreceptor (38). These differences in opsin localization may be attributed to the different severities of disease due to RPGR or RPGRIP1 loss and the degree of impact on ciliary transport. Because LCA is more severe than retinitis pigmentosa caused by RPGR loss, ciliary transport may be more affected leading to a more severe trafficking defect and the opsin expression pattern seen in RPGRIP1 KO organoids.

While CRB1 and RPGRIP1 KO organoids represent different genetic causes of LCA and exhibit different histological pathologies, both models converge on ER stress as a common degenerative pathway. At the later time points, both KO's exhibited induction of DDIT3, a key event in ER stress mediated cell death (98). Our results are consistent with previous reports that ER stress has been shown to be an important cause of cell death in various forms of neurodegeneration, including retinal degeneration, possibly due to the sensitivity of neurons to cell stress (105). In retinal degeneration, ER stress is a common mechanism of cell death due to misfolding and accumulation of mutant rhodopsin (106-108). While protein misfolding is a frequent cause of ER stress, photoreceptors have also been shown to induce DDIT3 and ER stress mediated in cell in

environmental models of excess light exposure (108, 109). The CRB1 and RPGRIP1 KO organoids described here differ from these causes of ER stress in that there is an absence of a critical protein, as opposed to accumulation of misfolding proteins or environmental stressors. Rather, based on the histological findings in these KO's, it is likely that ER stress resulted from improper protein trafficking to outer segments. In the case of CRB1 KO organoids, we have shown that RHO does not localize to outer segments, and is rather expressed in patches in the internal most part of the ONL. This finding and the role of CRB1 in establishing photoreceptor polarity suggest that opsins are not properly trafficked to the outer segments. Similarly, RPGRIP1 KO organoids also likely exhibit a protein trafficking defect. The complete absence of outer segment discs and predominantly cell body staining of opsins is also suggestive of a defect in trafficking of opsins and other phototransduction proteins. Improper protein trafficking has also been previously identified as a cause of ER stress and photoreceptor cell death in models of achromatopsia and LCA due to loss of Lrat (110-113). Specifically, cone opsin mistrafficking leads to ER stress and cell death in Lrat KO LCA mice and achromatopsia mouse models of Cnga3 or Cngb3 loss (111-113). These findings support opsin mistrafficking in CRB1 KO and RPGRIP1 KO organoids as a potential cause of ER stress and cell death. Because both LCA models described here induced DDIT3 expression and ER stress, targeting this pathway may decrease the degree of photoreceptor cell death and lessen the severity of visual impairment for patients. Inhibition of ER stress has been shown to promote photoreceptor survival in P23H rats, making this an attractive target for therapeutic intervention (114). However, because the P23H mutations leads to an accumulation of mutant rhodopsin, further studies are required to determine if inhibition of ER stress can attenuate photoreceptor degeneration resulting from protein mistrafficking, as well as the utility of targeting this pathway in retinal degeneration treatment.

## DATA AVAILABILITY

All fastq files and expression matrices can be found on GEO accession GSE152212.

## **Chapter 4: Single cell transcriptomic analysis of human stem cell derived OPCs**

### **Single-cell transcriptomic analysis reveals molecular diversity of PDGFR $\alpha$ + human oligodendrocyte progenitor cells**

Reworded content and figures/legends from:

Chamling, X., Kallman, A., Fang, W., Berlinicke, C., Mertz, J.L., Devkota, P., Morales Pantoja, I.E., Smith, M.D., Ji, Z., Chang, C., Kaushik, A., Chen, L., Whartenby, K., Calabresi, P.A., Mao, H-Q., Ji, H., Wang, T-H., Zack, D.J. Single-cell transcriptomic analysis reveals molecular diversity of PDGFR $\alpha$ + human oligodendrocyte progenitor cells. Under review.

#### **Abstract**

Demyelinating diseases such as multiple sclerosis can result from oligodendrocyte injury or loss, and remyelination-based treatment strategies would benefit from an improved understanding of oligodendrocyte development. To address this, we performed single-cell transcriptomics over a time course of human stem cell-derived oligodendrocyte precursor cell development. We utilized a genome engineered stem cell line expressing a tag under the PDGFR $\alpha$  endogenous locus to purify and analyze OPCs. We characterized the transcriptional heterogeneity of stem cell derived PDGFR $\alpha$ + OPCs and identified candidate regulatory factors controlling differentiation and myelination capacity. Specifically, we identified branch points separating oligodendrocyte and astrocyte cell fates and identified novel genes possibly involved in regulating this cell fate decision.

## Introduction

Myelin is essential to neuronal health and function in vertebrates, and it functions to both protect axons and enable rapid saltatory conduction (115). Multiple sclerosis and other myelin disorders can be either inherited or acquired, resulting from genetic mutation, toxic injury, or autoimmune insult, and these disorders often lead to severe disability (116). While treatment options exist to modulate demyelination, these drugs are unable to effectively promote remyelination. Remyelination strategies could provide more impactful treatment avenues would benefit from better understanding of the molecular mechanisms underlying development of oligodendrocytes (OLs), the glial cells responsible for myelinating the central nervous system (CNS). Transcriptomic and pathways studies have led to identification of compounds that could target oligodendrocytes capable of myelination, however these studies utilized primarily rodent oligodendrocyte precursor cells (OPCs) and OLs (33, 117-119). Importantly, many differences exist between human and rodent OPCs and OLs, including over 200 human OPC genes not expressed in mouse OPCs and the expression of *Ascl1*, which is critical for OL development from mouse neural precursors but dispensable in humans (35, 120). As a result, more detailed transcriptomic analysis of human oligodendrocyte lineage cells (OLLCs) could greatly benefit disease modeling and ability to identify drugs to promote myelination.

Studies of human OLLCs are severely limited by difficulty in obtaining sufficient numbers of purified cells, as primary OPCs are rare, difficult to isolate, and cannot be expanded following isolation (52). Alternatively, OPCs differentiated from human pluripotent stem cells (hPSCs) provide another system for studying human OPCs, however challenges still exist in identifying and purifying OPCs from mixed cell populations (121-124). In this study, we utilized a genome engineered human

embryonic stem cell (hESC) reporter system in which an identification-and-purification (IAP) tag expressed under the endogenous PDGFR $\alpha$  locus enables scalable differentiation and purification of PDGFR $\alpha$ + OPCs. Single cell capture via Dropseq and transcriptomic analysis was performed using this stem cell line at three time points over OPC differentiation (57). This single cell RNA sequencing (scRNAseq) and analysis enabled identification of transcriptionally distinct cell populations within the purified OPCs, thus revealing transcriptional heterogeneity of OPC populations and facilitating analysis of the various OPC differentiation pathways (57, 125). Comparing genes differentially expressed between OPCs and mature OLs identified pathways involved in OL maturation. Additionally, consistent with previous studies, we report the ability of PDGFR $\alpha$ + OPCs to generate astrocyte cells, as well as identification of PDGFR $\alpha$ + cells expressing mature astrocyte or oligodendrocyte markers (52, 53). We utilized the potential nature of the reporter OPCs and pseudotime analysis to characterize the trajectory of OPC development and the OL versus astrocyte lineages (77). This analysis identified OL or astrocyte enriched genes that could be involved in regulating OL versus astrocyte cell fate specification.

## **Methods**

### **Dropseq-based single cell capture and RNA-sequencing**

Drop-seq-based single cell RNAseq was performed as previously described by Macosko et al. (16). Barcoded microparticles were purchased from Chemgenes Corporations. During differentiation, large number of differentiating cultures are PDGFR $\alpha$ + on day 75, providing sufficient cell numbers for downstream analysis (121, 126). We observe a similar phenomenon with tdTomato expressing cells in our differentiation culture. Therefore, day 75 and two other time-points, two weeks apart were considered for time-course single cell capture. Since MACS purification and Drop-

seq could not be timed on the exact intended day, we ended up using cells from day 77, day 89 and day 104. The differentiating cells were MACS purified for Thy1.2 expression. Each time-point is from single batch of differentiation. Small fraction of the purified cells was used for FACS-based analysis to confirm that >90% of them were tdTomato+. Cells were MACS purified 2-3 times until ~90% purity was achieved. Using the microfluidic device, the purified reporter cells were captured into a ~1 nL size droplets containing barcoded nanoparticles and lysis buffer. Generated droplets were broken with perfluorooctanol (Sigma, 370533) in 30 ml of 6× SSC. The beads were then washed, reverse transcribed, PCR amplified, and the amplified cDNA quantified using a BioAnalyzer High Sensitivity Chip (Agilent). The cDNA was then fragmented and amplified for 3' prime end sequencing with the Nextera XT DNA sample prep kit (Illumina). cDNA and libraries for each sample were prepared independently, and an equimolar amount of each library was then pooled together for sequencing. The libraries were purified, quantified, and then sequenced on the rapid flow chip in Illumina HiSeq 2500. From the three independent timepoints, a combined total of ~4,800 purified cells were captured.

### **Quality control and clustering**

The principal component analysis (PCA) and t-distributed stochastic neighbor embedding (tSNE) analyses were performed using a previously published R package, Seurat (76). As a quality control, only cells that had a minimum of 250 mRNA molecules and a maximum of 20% mitochondrial RNA were used for analysis. In order to eliminate probable doublets from the dataset, we bioinformatically filtered out cells with >30,000 unique molecular identifier (UMIs) (Figure S3a). Additionally, we removed cells that exhibited 1) expression of less than 250 genes or 2) greater than 20% mitochondrial gene content. The remaining 3271 cells were used for further bioinformatic analysis.

Genes that were expressed in a minimum of 3 cells were included for the analysis. 1874 highly variable genes were input for PCA analysis, and the 16 statistically significant PC's were used for clustering and t-SNE analysis. 1266 enriched genes were used to generate the expression heatmap. A gene that showed positive fold change with significant p value in a population when compared to all other populations is considered "enriched".

### **Pseudotemporal trajectory analysis**

Time-series analysis to generate a pseudotemporal trajectory was performed using an unsupervised differential gene expression test based on sample age in Monocle, following previously published detailed instructions (77). The top 752 genes differentially expressed based on age were used for ordering and trajectory reconstruction. Differential gene expression was performed on each node of the resulting trajectory to identify genes with branch-dependent expression. Differential gene expression was performed using either Seurat or Monocle.

### **Calculation of Spearman correlations and human mouse overlap assessment**

Total expression of all the genes expressed in both our dataset and the previously published snRNAseq dataset (13658 total genes) was used to normalize gene expression in each cell (127). The normalized expression was averaged across each population. 1195 variable genes expressed in both datasets were then used to calculate spearman correlation between each population. To combine all the oligodendrocyte subpopulation as one population, expression was weighted by number of cells in each sub-population. Similar weighted average was also used to combine the two astrocyte sub-populations. For the comparison with bulk RNAseq dataset, 767 highly variable genes from each human tissue-type published by Zhang et al. was compared to

each of our population's averaged normalized expression (128). For comparison with mouse cells, all the genes expressed in each of our clusters were compared to the genes from each of the mouse CNS cell-type previously published (119).

To assess the overlap of enriched genes in our hESC-derived OLLCs, ALCs, OPCs, and endothelial/pericyte cells to that of the enriched genes in the corresponding population from mouse dataset, we assigned clusters 0,1, and 3 as OPCs; 4,7, and 8 as OLLCs; 2,5,6, and 9 as ALCs; and 10 as endo/peri. All 1266 differentially expressed genes used for the expression heatmap (Figure 4b) were used for the comparison. From the mouse dataset<sup>3</sup>, genes expressed at levels > 20 FPKM and >5-fold relative to the average expression in all other populations, were considered enriched (119).

## **Results**

### **Single cell transcriptome analysis of PDGFR $\alpha$ + reporter OPCs**

Development of scRNAseq technologies has allowed for the ability to profile thousands of single cells and identify transcriptional heterogeneity within cell populations (57, 125, 129). We utilized Dropseq, a microfluidic based single cell capture platform, to transcriptomically analyze differentiating OPCs and elucidate the gene expression changes associated with OL development and maturation (57). Reporter cells over three time points during *in vitro* differentiation, days 77, 89, and 104, were independently purified via MACs to obtain a 90% pure population of PDGFR $\alpha$ -tdTomato+ cells for single cell capture and RNA sequencing. These three stages yielded a total of 3271 cells after quality control filtering (Supplementary Fig. 1A-B). Cells were clustered using unsupervised t-distributed stochastic neighbor embedding (t-SNE) into 12 transcriptionally distinct cell populations (Fig 1A-B).

We also utilized spearman correlations with previously published single nucleus and bulk RNA sequencing to compare our dataset to primary human and murine CNS

cells (Fig. 1C and Supplementary Fig. 1C) (119, 127, 128). The correlations, gene expression patterns, and cell-type specific marker genes in Table 1 suggested that clusters 0, 1, and 3 are OPCs and clusters 5, 6, 9, and 2 are astrocyte lineage cells (ALCs), while more mature OLLCs correspond to clusters 4, 7, and 8 (Fig. 1, Supplementary Fig. 1C). Additionally, cluster 8 exhibited enrichment of the mature OL markers *MAG*, *MOG*, and *ZNF488*, indicating this population may be more mature than the OLs in clusters 4 and 7, which are likely newly formed OLs (nfOLs). Importantly, our in vitro differentiated OL populations were highly correlated with 6 previously described sub-populations of human brain OLs (Fig. 1C) (127). We also identified clusters 2, 5, 6, and 9 to have relatively higher correlation with fetal astrocytes (Supplementary Fig. 1C). Cluster 2 also exhibited high correlation with mature astrocytes, as well as enrichment for mature astrocyte markers including *SPARCL1*, *AQP4*, *IGFBP7*, *AGT*, and *EDNRB* (Fig. 1C, Supplementary Fig. 1C, Table 1) (128, 130). Proliferative genes associated with fetal astrocytes, including *TOP2A*, *HIST1H4C*, *PCLAF*, *HMGB2*, *NUSAP1*, *MKI67* and *TMSB15A*, were enriched in clusters 5, 6, and 9, but depleted in cluster 2 (Table 1). Additionally, cell cycle analysis revealed that the majority of the cells in clusters 5, 6 and 9 were in G2M or S phase, whereas the majority of the cells in clusters 2, 4, 7 and 8 were in G1 phase (Supplementary Fig. 1E). This data further confirms that cluster 5, 6 and 9 represent proliferative fetal astrocytes and cluster 2 is more akin to mature astrocytes.

Cluster 10, which was distant in the t-SNE space, exhibited higher correlation with endothelial cells and pericytes, in addition to enrichment for pericyte marker genes (*COL1A1*, *COL1A2*, *COL3A1*, *ATAC2*, *PDGFR $\beta$* ) and the endothelial marker gene *ANXA2* (Fig. 1C, Supplementary Fig. 1C, Table 1) (131, 132). This gene expression pattern suggests that this cluster could represent the VLMC-pericyte cells that are reported to arise from PDGFR $\alpha$ + precursors (133). This cluster exhibited expression of

a few mature astrocyte markers (*SLC40A1*, *IGFBP7*, *SPARC*), and except for one or two cells, no OPC markers were detected (Fig. 1D, Table 1). It is also possible that this cluster could represent contaminating PDGFR $\alpha$  negative cells in the purified population.

Of all the single cells analyzed, 901 (27.5%) expressed *GFAP* and 733 (22.4%) expressed *MBP*, corresponding to ALCs and OLLCs, respectively (Supplementary Fig. 1D). As cells matured, the proportion of OPCs decreased while the *MBP*<sup>+</sup>/*PLP1*<sup>+</sup> and *GFAP*<sup>+</sup>/*AQP4*<sup>+</sup> populations increased in prevalence, supporting the finding that PDGFR $\alpha$ <sup>+</sup> OPCs are able to differentiate into astrocytes and oligodendrocytes *in vitro* (Supplementary Fig. 1D and G) (52). Analysis of cells separately at each time point revealed that OPCs, OLs, and astrocytes are present at each time point (Supplementary Fig. 1H-J). While cells purified at the later time points are more enriched in the mature clusters, each cluster included cells over all three stages, thus confirming that purified hPSC-derived OPCs are heterogeneous with respect to their degree of differentiation even within the same *in vitro* stage (Supplementary Fig. 1F).

### **Validation of astrogenic potential in OPCs**

To confirm that the ability of OPCs to form astrocytes was not a feature resulting from the reporter cell line or purification method, we also characterized OPCs differentiated from a second, non-reporter iPSC line, after 60 days in culture and purified using a PDGFR $\alpha$  antibody (Supplementary Fig. 2A-B). Very few cells expressed mature OL (*MBP*, *PLP1*) or astrocyte (*AQP4*) markers, which was unsurprising considering the time point (Supplementary Fig. 2C). Despite the lack of mature markers, the OL related genes *CNP* and *TCF7L2*, as well as transcription factors known to promote astrocyte development (*SOX9*, *NFIA*, and *NR2F1*), were enriched in day 60 cells. Additionally, many of these PDGFR $\alpha$ <sup>+</sup> cells expressed *GFAP* (Supplementary Fig. 2C-D). As a second control, we also performed scRNAseq with day 89 reporter cells purified using

O4-antibody conjugated microbeads. Similarly to the other datasets, a subpopulation of these O4+ cells also expressed astrocyte markers (Supplementary Fig. 2E).

### Identification of cell-type enriched genes

We next examined the clusters for highly enriched and differentially expressed genes, and found that the majority of differentially expressed genes in the OLLC and ALC populations were consistent with previous publications (119, 128). For example, *MBP*, *PLP1*, *CNP*, *CLDN11*, *UGT8*, *BCAS1*, *SIRT2*, *MOG*, *MAG*, *TNR*, *ENPP6*, and *CHN2* were enriched in the OLLCs; and *GFAP*, *CLU*, *AQP4*, *ID3*, *EDNRB*, *MGST1*, *AHCYL1*, *EZR*, *HSPB8*, *SPARC*, *DTNA*, and *FABP5* were enriched in the ALCs (Table 1, <http://zacklab.org/OPCs/>). We also report expected expression patterns for genes shown to be enriched specifically in human, but not mouse, OLs and astrocytes such as *APCDD1*, *HMGCS1*, *PMP2*, and *WIF1* (128, 134). We then sought to compare genes enriched in our hESC-derived OLLCs, ALCs, and OPCs to those enriched in the murine cell populations (119). While many known marker genes were enriched in both murine and human cells, we report some differences in gene expression enrichment (Supplementary Fig. 3A-D). In contrast to previous studies, we found OL enrichment of genes including *KCTD12*, *SLC7A14*, *HMGCS1*, *SPOCK1*, *FAM13C*, *FAM131C*, *TMEM206*, and *KIF21A* (Fig. 1D, Supplementary Fig. 3A, Table 1). *HMGCS1* has not been shown to be expressed in murine CNS cells, however it is also important for cholesterol biosynthesis and myeline production in the zebrafish CNS (119, 135). Contrary to the OL enrichment in our dataset, other human CNS data has shown its enrichment in fetal astrocytes (128). *KCTD12*, *TMEM206*, *FAM131C*, *FRMD4B* and *APCDD1* were OL-enriched in our dataset, but bulk RNAseq of purified murine CNS cells has shown *KCTD12* and *TMEM206* enrichment in microglia; *FAM131C* enrichment in neurons; and *FRMD4B* and *APCDD1* expression specifically in endothelial cells (119).

Additionally, while previous studies have shown specific expression of *CD9* in myelinogenic OLLCs, we report relatively ubiquitous *CD9* expression across all clusters, suggesting that *PDGFRα*<sup>+</sup>/*CD9*<sup>+</sup> expression is not specific to only myelinogenic precursors within the stem cell-derived OPC system (Fig. 1D) (52). In addition to protein coding genes, we identified numerous differentially expressed primary microRNAs (pri-miRNAs) (Supplementary Fig. 2H). Specifically, miR219-A2 was enriched in OL clusters whereas miR100HG and miR99AHG were astrocyte-enriched. These differentially expressed pri-miRNAs could be involved in regulating the developmental decision for an OPC to form either an OL or an astrocyte.

### **Trajectory analysis of the bi-potential nature of *PDGFRα*<sup>+</sup> cells**

We next utilized the Monocle R package to create a pseudotemporal trajectory of cell fate specification in *PDGFRα*<sup>+</sup> cells over development (77). This trajectory presented two main cell fates for the precursor cells, suggesting that OPCs have the potential to form two distinct cell populations (Fig. 2A). Identification of differentially expressed genes and transcription factors (TFs) and the main node using the Branch Expression Analysis Modeling regression model enabled us to designate path II as OLLCs and path III as ALCs (Fig. 2B-C). In analyzing TFs specifically, *HES1*, *EGR1*, *ZFP36L1*, *NFIA*, and *JUNB* were enriched in ALCs, whereas *SOX10*, *SOX4*, *SOX6*, *TSC22D1*, and *RBPJ* were OLLC enriched (Fig. 2C). This data suggests that these TFs could be involved in OPC cell fate specification.

In assessing the specific cell populations of the trajectory, we identified 7 states across development (Fig. 3A). State 1 was comprised of precursor cells, state 2 astrocytes, and state 6 OLs. The expression of *MBP* and *PLP1* over pseudotime showed an enrichment in state 6 OLs, while *GFAP* and *AQP4* expression over pseudotime showed an enrichment in state 2 astrocytes (Fig. 3C). In analyzing smaller

sub-branches along path II towards mature OLs, states 5 and 7 diverged from the OL trajectory and exhibited enrichment of astrocyte markers (*GFAP*, *AQP4*, *NFIA*, *SOX9*), instead of OL markers (*PLP*, *MBP*, *SOX10*, *TCF7L2*, *OLIG2*, *NKX2.2*) (Fig. 3B, Supplementary Fig. 4B). We performed correlation between each branch, and unsurprisingly the state 5 and 7 cells were more highly correlated with state 2 astrocytes than state 6 OLs (Supplementary Fig. 4B). Additionally, cells from the astrocyte cluster in the t-SNE (cluster 2) were present in states 2, 5, and 7 (Supplementary Fig. 4C). To validate this bipotential cell fate in a second system, we performed parallel pseudotime analysis in the day 89 O4+ purified reporter cells. Similarly, this trajectory indicated two main branches, one representing the OL fate and the other the astrocyte fate, as well as the same trends in marker gene expression over pseudotime (Supplementary Fig. 4D-F).

Finally, utilized the same differential expression analysis regression model, we examined differential gene expression at nodes 1 and 2 and between states 2 and 6 to identify genes of potential interest (Fig. 3D-E, Supplementary Fig. 5A-C). In addition to the previously described TFs that could be important for OPC/OL/astrocyte differentiation, including *SOX10* and *TCF7L2*, we identified a number of TFs whose roles in development are less well characterized. Specifically, *ZEB2*, *TSC22D4*, *ARID4B*, *PARP1*, *E2F3*, and *ARHGAP35* were enriched in OLs, while *HES1*, *FOSB*, *NFIA*, *NR2F1*, and *ZFP36L1* were enriched in astrocytes. We also identified TFs such as *SOX4*, *SOX11*, *MLLT11*, *RBM22*, *ZNF711*, *EZH2*, and *DACH2* as depleted in ALCs and slightly enriched in OLs (Fig. 3D). A subset of these genes were also enriched in the day 60 hPSC-derived OPCs (Supplementary Fig. 2C). Finally, the purified PDGFR $\alpha$ + cells from each time point (days 77, 89, and 104) were present across all branches of the trajectory, supporting the claim that these cells are heterogeneous both

transcriptionally and developmentally, to the degree that even some day 77 cells were already relatively mature (Supplementary Fig. 5C).

## Discussion

In this study, we have characterized the transcriptional diversity and heterogeneity of PDGFR $\alpha$ <sup>+</sup> OPCs using scRNAseq over a time course of differentiation of reporter OPCs, as well as a second non-reporter cell line. We identified distinct cell clusters, most of which represented OPCs and cells committed to OL or astrocyte cell fate. This is consistent with previous reports that OPCs are capable of developing into either astrocytes or OLs *in vitro* (52). Because previous studies have shown that only OPCs and pre-OLs, not mature OLs, express PDGFR $\alpha$ , the identification of PDGFR $\alpha$ <sup>+</sup>/tdTomato<sup>+</sup> cells expressing mature astrocyte and OL markers was unexpected (Fig. 1, Table 1) (33, 115, 122, 136). Mature astrocyte markers such as the synapse-inducing protein (*SPARCL1*) and transmembrane proteins (*CLU* and *SPON1*) were detected and highly enriched in the astrocyte cluster (128). On the other hand, the OL cluster was enriched for genes associated with myelin production including *MBP*, *MYCRF*, *MAG*, and *MOG* (Table 1). Of note, the *PDGFR $\alpha$*  transcript was not detected in the clusters representing these mature cell types (Fig. 1D). This could be explained by presence of the PDGFR $\alpha$  protein, but not transcript, at the time of purification, a longer half-life of tdTomato and Thy1.2 enabling purification beyond the window of PDGFR $\alpha$  expression, or low abundance of the *PDGFR $\alpha$*  transcript in mature cells leading to drop out in the single cell dataset (57, 125, 129, 137, 138).

The identification of transcriptionally distinct cell clusters within the PDGFR $\alpha$ <sup>+</sup> population was made possible by scRNAseq and would be undetectable by bulk RNAseq strategies. This analysis enabled identification of several novel human-specific OL (*KCTD12*, *SLC7A14*, *HMGCS1*, *SPOCK1*, *FAM13C*, *FAM131C*, *TMEM206*, and

*KIF21A*) and astrocyte (*S100A10*, *CD99*, *ID2*, *CRYAB*, and *CA2*) marker genes.

Interestingly, we identified some OL and astrocyte specific genes (*KCTD12*, *HMGCS1*, *FAM131C*, *APCDD1*, *S100A10*, *CD99*, and *ID2*) that have been shown to be expressed in primary microglia, neurons, and endothelial cells (119, 128). This could be a feature of differences between *in vitro* differentiated cells and their *in vivo* counterparts, or lower sequencing depth in scRNAseq compared to bulk RNAseq. However, it is also possible that immunopanning for primary cells from a mixture of dissociated brain cells led to contamination of OL and astrocyte populations with microglia and endothelial cells. Identification of such contaminating cell populations is now possible using various scRNAseq methods.

Because of the large window of PDGFR $\alpha$  expression in OPCs, we were able to utilize pseudotemporal trajectory analysis to better understand OPC differentiation. This analysis revealed that OPCs have two major cell fate decisions corresponding to the OL and astrocyte lineages. While t-SNE clustering identified a small population of cells expressing endothelial/pericyte markers, this population was not identified in the trajectory (Fig. 1, Table 1). The development of oligodendrocytes and astrocytes from our PDGFR $\alpha$ +tdTomato+ cells is consistent with findings from *in vitro* cultured primary human OPCs, but contrasts with murine studies showing that Pdgfra+ mouse OPCs can form OLs, neurons, or VLMC-pericytes, but not astrocytes *in vivo* (52, 133). To our knowledge there are no existing studies of the ability of *in vitro* cultured Pdgfra+ mouse OPCs to form astrocytes. While our results derive from an *in vitro* culture system and must be confirmed *in vivo*, our findings suggest that human OPCs can differentiate into astrocytes (Fig. 2, Supplementary Fig. 3)

We have also identified TFs that could be important for directing differentiation of OPCs to either OLs or astrocytes. Various TFs, such as *ZEB2*, *TSC22D4*, *ARID4B*, *PARP1*, *E2F3*, *SOX10*, *TCF7L2*, *TSC22D1*, *RBPJ*, *ARHGAP35*, *SOX4*, *SOX11*,

*MLLT11*, *RBM22*, *ZNF711*, *EZH2*, and *DACH2*, were continuously upregulated in OLs and downregulated in astrocytes. On the other hand, *HES1*, *EGR1*, *FOSB*, *NFIA*, *NR2F1*, *ID3*, *KLF6*, and *ZFP36L1* were enriched in astrocytes and depleted in OLs. It is possible that these sets of TFs could drive specification OL or astrocyte cell fates. The relationships between most of these TFs and OPC differentiation have not been studied, making future studies necessary to ascertain the roles of these TFs in OPC development. The functions of *SOX10* and *TCF7L2* in OL development and *NFIA* and *NR2F1* in astrocyte development have been well characterized, in addition to the recent identification of the role of *ZFP36L1* in OL/astrocyte cell fate specification (139-141). Our identification of these TFs lends support to the possible role of the newly identified TFs in OPC development, however further loss and gain of function studies are necessary to validate and determine their specific impacts on development of OPCs, OLs, or astrocytes.

While Dropseq only captures polyadenylated RNAs and is thus unable to capture mature miRNAs, pri-miRNAs contain polyA tails prior to cleavage by Drosha and are thus able to be captured in this system. MiRNAs, in addition to regulatory genes and TFs, have been shown to be important for OPC specification and differentiation (142-144). To this end, we identified *miR219-A2* as highly enriched in the OL cluster, and it has also been shown to be important for myelination and re-myelination in mice (35, 117, 143-145). The reporter system described here and single cell transcriptomics could enable future studies of ALC and OLLC specific miRNAs in OPC development.

While human and murine OPCs and OLs have similar gene expression patterns and conserved pathways, important species-specific differences exist with regard to their transcriptomes, development, and regeneration (146). For example, gliogenesis in humans begins during gestation and myelination can continue until age 22, whereas rodent gliogenesis occurs postnatally and myelination is complete by day 60 (147, 148).

Additionally, in vitro expression of *Ascl1* and *Fgf2* promote development of OLs from OPCs in rodents, but not humans (35). Furthermore, animal models of MS are capable of regenerating myelin from newly formed OLs, while human patients have diminished capacity to generate new OLs and rather the limited remyelination likely originates from pre-existing OLs (149). Because of these differences, better understanding of human OL maturation is critical for improved disease modeling and drug discovery efforts. We hope that the hOPC purification system described here along with our scRNAseq dataset (<http://zacklab.org/OPCs/>) will help provide the basis for ongoing and future studies that will more fully define the molecular mechanisms of human OL differentiation, maturation and myelination.

### Figure 3: Pseudotemporal trajectory of differentiation based on single cell transcriptomes.

**A)** Ordering cells along the trajectory divides the population into seven different states. State 1 cells are OPCs, state 2 cells are astrocytes, and state 6 cells are oligodendrocytes. **B)** Expression of OL and astrocyte markers within the trajectory further confirms Path III as the astrocyte and Path II as oligodendrocytes lineage cells. Astrocyte makers (*GFAP*, *AQP4*, *SOX9*, *NFIA*) are highly enriched in Path III and in the smaller branches that emerge from path II. OLLC markers (*SOX10*, *MBP*, *PLP*, *TCF7L2*) are enriched in Path II, but not in the smaller branches. **C)** Pseudotemporal expression pattern of OL and astrocyte genes show that the OL genes, *MBP* and *PLP1*, have similar kinetic trend and both are enriched in state 6 cells. The astrocyte marker *GFAP* is modelled to be expressed earlier than *AQP4*, although both are enriched in state 2 cells. **D-E)** Kinetic heatmap of the most differentially expressed non-transcription factor **(D)** and transcription factor genes **(E)** between state 6 (oligodendrocyte cells) and state 2 (astrocyte cells) identified by BEAM and clustered based on their expression pattern.

## Supplementary Materials

### Supplementary Figure 1: scRNAseq analysis of the purified PDTT reporter OPCs

**separated by different differentiation time-points. A-B)** Quality control metrics applied to the scRNA seq data of MACs purified PD-TT derived OPCs. **A)** Violin plot showing number of UMIs by age. In order to remove probable doublets, cells with UMI above 30,000 were removed from the analysis. **B)** Percent mitochondrial gene content per cell. Cells with greater than 20% mitochondrial gene content were also removed from analysis. **C)** Spearman correlation of single cell transcriptome-based clusters with RNAseq data from primary mouse brain cells and primary human brain cells. **D)** table showing number and percentage of cells expressing OL and astrocyte markers at different time-points. **E)** Single cell transcriptome-based cell-cycle analysis. Majority of the cells in cluster 5,6 and 9 are at G2M of S phase, and majority of the cells in cluster 2, 4 and 8 are at G1 phase. **F)** Cells in the t-SNE plot labelled by day at which they were purified (day 77, 89, or 104). Although some enrichment of day 77 cells in OPC and day 104 cells in the mature clusters is noticeable, each cluster consists of cells from all three ages. **G)** A bar graph depicting the frequency of each cluster per time point. Overall reduction of progenitor (0,1,3) clusters and increase in mature clusters i.e OLC, ALC, and Endo-peri clusters is apparent. **H-J)** t-SNE based unsupervised clustering of single cells captured from PDGFR $\alpha$ +tdTomato+ reporter OPCs at different stages of differentiation (day 77, day 89, and day 104). Cluster specific enrichment of various OL and astrocyte markers indicate OLLC and ALC subgroups of PDGFR $\alpha$ + cells in each time-point.

Figure 39

**Supplementary Figure 2: Bioinformatic analysis of the hiPSC-derived PDGFR $\alpha$ +**

**OPCs and O4+ cells A)** hiPSC-derived, day 60 OPCs were stained with antibody

against PDGFR $\alpha$  and FACS-purified. Single cells from the FACS-purified samples were captured using the 10X-genomics platform, and their transcriptome was sequenced and analyzed. **B)** t-SNE based unsupervised clustering divided cells into 5 clusters. **C)**

Enrichment heatmap showing expression patterns for each cluster of previously reported OL and astrocyte markers. Enrichment of various OL and astrocyte genes is apparent.

**D)** Scatterplot mapping cells that express PDGFR $\alpha$  and GFAP. Numerous cells express both the genes. **E)** PD-TT cells at day 89 of differentiation were MACS purified using O4

beads and processed for scRNAseq with Drop-seq. t-SNE based unsupervised clustering and heatmap showing expression patterns of OL and astrocyte markers of day 89 PD-TT cells enriched using O4 microbeads.

*Figure 40*

**Supplementary Figure 3: Species-specific similarity and differences between genes enriched in our hESC-derived populations vs primary mouse cells. A-D)** Venn diagram depicting the overlap of genes enriched in human vs mouse **A) OLLCs** **B)** ALCs **C) OPCs**, and **D) Endothelial/pericytes**, with examples of overlapping and different genes. **E)** Heatmap of pri-microRNAs captured by scRNAseq analysis. miR219 is enriched in OL clusters, miR99AHG and miR100HG are enriched in astrocyte clusters.

Figure 41

**Supplementary Figure 4: Monocle-2 analysis of the PDDT reporter cells purified with Thy1.2 or O4+ microbeads. A)** Within the trajectories derived from the PDDT OPCs purified with Thy1.2 microbeads, OLLC markers (OLIG2 and NKX2-2) show higher expression in Path I and II, but not in Path III or the smaller branches that emerge along Path II. **B)** Scatterplot showing the average gene expression of the cells in astrocyte vs oligodendrocyte states. Each dot represents a gene and axes are average number of transcripts per cell. Cells from the small branches (state 5 and 7) have higher correlation with astrocytes (state 2 cells) than oligodendrocytes (state 6 cells). Inset shows cells at different states. **C)** Overlay of cells from each cluster from figure 4a onto the pseudo-temporal trajectory showing where in the trajectory the cells from each cluster are located. Cells from cluster 0, 1, and 3 make up the majority of Path I population. Cells from astrocyte cluster (cluster 2) make up the majority of population on Path III (state 2 cells) and the sub-branches within Path II (state 5 and 7 cells). Cells from cluster 4 and 8 are located at the end of Path II (state 6 cells). Cells from cluster 10 are located at the end of Path III or state 2 cells. **D)** Developmental trajectories of the O4 microbead enriched day 89 reporter OPCs, generated using Monocle-2. Developmentally younger cells (A) represent OPCs and fall on shorter branch. OPCs have two prominent developmental paths B and C. **E)** Expression of OL and astrocyte markers within the trajectory show enrichment of astrocyte markers (GFAP, AQP4) on Path B and OLLC markers (MBP, PLP1) on Path C. **F)** Pseudotemporal expression pattern of OL and astrocyte genes showing kinetic trend of the OL, (MBP and PLP1) and astrocyte (GFAP and AQP4) marker genes.

*Figure 42*

Fig. S8

**Supplementary Figure 5: Heatmap of the most differentially expressed genes between different sub-branches of the monocle-2-based trajectories. A-B)**

Differential heatmap capturing the most differentially expressed genes **(A)** and transcription factors **(B)** between Paths II (oligodendrocytes) and III (astrocytes) identified by BEAM and clustered according to their expression pattern. Analysis of differential expression at node 2 represents genes from sub-branch A vs C **(B)**, and node 1 represents sub-branch B vs D **(A)**. See inset on the bottom right for labelling of nodes and sub-branches. **C)** Cells in each path of the trajectory are labelled by day at which they were purified (day 77, 89, or 104). Although some enrichment of day 104 cells is seen in the mature clusters, each path consists of cells from all three ages.

## Chapter 5: Conclusions and Future Directions

Collectively, the work described in this thesis utilized human stem cell systems to gain insights into multiple facets of human retinal health and disease. While mouse models have provided many important insights, there are distinct difference between human and murine biology that necessitate human models. Utilizing human models of development and disease allows for identification of similarities with mouse models and features unique to human models. In the case of NRL loss, we identified many of the same transcriptional changes in murine and human photoreceptors, specifically decreased expression of *RHO*, *GNAT1*, *NR2E3*, *ROM1*, *RCVRN*, *GNB1* and *CNGA1* (17, 18). However, murine *Nrl* null photoreceptors still exhibit *Sag* expression, while *SAG* expression is absent in human NRL null photoreceptors. Additionally, human NRL null photoreceptors form 2 distinct S-opsin expressing populations which may explain the ESCS phenotype of enhanced cone function combined with some degree of retinal degeneration (12). These 2 *OPN1SW*<sup>+</sup> populations have not been identified in *Nrl* null mice, however this may stem from lack of single cell transcriptomic studies of *Nrl* null mice. Further studies of *Nrl* null photoreceptor at the single cell level would be helpful to identify if these populations also exist in mice. In addition to photoreceptor development, modeling photoreceptor degeneration can also provide important insights. In the case of LCA, mouse models of *Crb1* and *Rpgrip1* loss highlight both similarities and differences to the human models described here. In the case of *Crb1* mice, retinas exhibited outer limiting membrane aberrations and rosette formation, but do not recapitulate the human phenotype of a thickened ONL (92, 101). The retinal organoid model of *CRB1* loss, however, did recapitulate the *in vivo* ONL thickening. Additionally, *CRB1* KO organoids exhibited aberrant *RHO*<sup>+</sup> expression, a phenotype not described in *Crb1* KO mice. In the case of *Rpgrip1* KO mice, *RPGRIP1* KO organoids recapitulate a similar phenotype of abnormal outer segment morphology, with human *RPGRIP1* KO photoreceptors

completely lacking outer segment discs (102, 103). Of the human models described here, OPC development is possibly the most significantly different from murine OPCs, with human OPC lineage cells being bipotential in terms of their ability to develop into astrocytes or oligodendrocytes. As such, human models of OPC development can identify gene expression changes important for skewing development toward oligodendrocytes and MBP expression. Identification and small molecule manipulation of oligodendrocyte development and myelin production could help promote re-myelination of neurons *in vivo*.

While identifying similarities and differences with mouse models highlights the importance of characterizing human models, arguably more significant insights from human models stem from the possibility of identifying avenues for therapeutic intervention in disease. For ESCS, targeting the rod photoreceptor population could help alleviate the phenotype. Because rods in human retinal organoids seem to result from a lack of the rod or cone gene expression programs and reintroduction of NRL led to expression of RHO, gene therapy to reintroduce NRL could potentially restore some rod function. On the other hand, LCA has extensive genetic heterogeneity that could benefit from a strategy targeting degenerative pathways as opposed to a specific gene. This study identified DDIT3 induction and ER stress as a common degenerative pathway in LCA photoreceptors. Studies of other human models of LCA or retinitis pigmentosa could reveal the extent of ER stress involvement across genetically different causes of photoreceptor cell death. Therapeutically targeting ER stress could help alleviate or slow photoreceptor degeneration, thus preserving some visual function for retinal degeneration patients.

Despite the insights into photoreceptor development and degeneration from this study, critical questions remain to be answered. In the case of photoreceptor development and the putative role of MEF2C, further studies are required to ascertain

the role of MEF2C in cone development and maturation. Specifically, knockdown studies of MEF2C are required to determine if its loss alters the distribution of rods and cones or if cones do not properly mature in its absence. Additionally, in the case of cdc, it is important to determine if induction of MEF2C expression could lead cdc to look more akin to the "normal" S cone population. For LCA and the utility of targeting ER stress to alleviate degeneration, it is critical to analyze other photoreceptor degenerations for ER stress involvement. While this study found a common pathway in two LCA models, over 20 genes are known to cause LCA and many more cause retinitis pigmentosa (RetNet). As such, more widespread generation and characterization of human models of photoreceptor degeneration are necessary. Finally, the link between CRB1 and RPGRIP1 loss and ER stress warrants further elucidation. While ER stress often results from accumulation of misfolded proteins, the mutant CRB1 and RPGRIP1 proteins in the described models would be expected to be degraded (98). ER stress can also result from perturbation of various other cell functions, and in this system, improper protein trafficking seems a likely cause of DDIT3 induction. Because photoreceptor function depends on trafficking opsins and various other phototransduction proteins to the outer segments, it is possible that loss of CRB1 or RPGRIP1 impair this function and lead to ER stress. Further studies of ER dynamics in these degeneration models and others can reveal important insights into how to combat ER stress and photoreceptor death in treating various forms of retinal degeneration.

## **Curriculum Vitae**

**Alyssa Kallman**

### **Education**

University of California, Los Angeles

*B.S, Microbiology, Immunology, and Molecular Genetics  
Magna Cum Laude*

Johns Hopkins University, School of Medicine

*PhD Candidate, Human Genetics*

### **Research Experience**

- Utilized CRISPR/Cas9 and human stem cells to engineer organoids for analysis of genetic retinal disease and identification of novel therapeutic targets
- Mentored various scientists in stem cell derived organoid culture and computational analysis techniques
- Use of the R programming language to analyze large single cell RNA sequencing datasets for data visualization and presentation in lecture-style and poster presentations
- Immunohistochemical analysis and imaging of retinal organoids to observe retinal architecture and photoreceptor morphology
- Collaborated with scientists in bioinformatics, pathology, and engineering departments at JHU and retinal degeneration researchers at the Cleveland Clinic and University of Wisconsin
- TA for graduate pathobiology course

### **Consulting Experience**

- Johns Hopkins Graduate Consulting Club 2019 Healthcare Case Competition
- Johns Hopkins Graduate Consulting Club 2018 Fall Case Competition

### **Awards**

- Visual Science Training Program Graduate Fellowship

### **Publications**
